 Striped Bass Technical Committee
## 2001 Stock Assessment Report

 for
## Atlantic Striped Bass

October 2001

The ASMFC Striped Bass stock assessment sub-committee and Technical Committee met in August 2001 to evaluate the status of the striped bass resource. The assessment includes the Hudson, Delaware, Chesapeake and mixed coastal stocks. The first analytical assessment using virtual population analysis (VPA) was conducted in 1997 (for years 1982-1996) and reviewed by the $26^{\text {th }}$ Stock Assessment Review Committee at the Northeast Fisheries Science Center. The results of the review were reported in the proceedings of the $26^{\text {th }}$ Northeast Regional Stock Assessment Workshop ( $26^{\text {th }}$ SAW): SARC Consensus Summary of Assessments (NEFSC Ref. Document 98-03). This report represents the latest in the series of annual assessments with the inclusion of the 2000 catch and survey data.

## Commercial Fishery

Commercial landings in 2000 totaled 1,057,712 fish and 6,620,429 pounds ( $3,003 \mathrm{mt}$ )
(Table 1, Table 2). The landings represent a decline of 46,101 fish and increase of 137,189 pounds compared to 1999 (Table 8). The Chesapeake Region (Maryland, PRFC, and Virginia) accounts for most of the commercial harvest, $73 \%$ by weight and $87 \%$ by number (Table 3). Overall, commercial harvest represented $36 \%$ by number and $28 \%$ by weight of total harvest removals in 2000, and $23 \%$ by number of the total catch (harvest + discard) (Figure 1, Table 2). Commercial harvest was primarily fish of ages 4 to 6 ( $67 \%$ of commercial harvest).

Commercial discards were estimated using the same method as in previous years. The estimation was based on the ratio of commercial to recreational released fish tag recovery data scaled by total recreational discards. However, a number of procedural changes resulted in some substantial differences in the discard estimates for 1998 to 2000, affecting both the estimate of total discards, the estimate of discard mortalities, and the distributions at age (Table 9). The total estimated discards changed due to 1 ) calculating the tag ratio value by area (Chesapeake and Coast) to account for area specific differences in the recovery ratio and 2) incorporating systemspecific discard estimates for the Hudson and Delaware Rivers. Overall discard mortality changed due to incorporation of region-specific (Chesapeake and Coast) discard gear proportions for 1998 - 2000. Previously (1982-1997), total discards were allocated to gears based on the overall distribution of tag recoveries by gear. The distribution of discards by age also changed, due to separation of available gill net discard age distributions into drift and anchor gill net categories rather than combining all gill nets. Total commercial discards losses for 2000 were
estimated as 386,884 fish, representing $8 \%$ of total removals in number (Figure 1, Table 2, Table 4, Table 9). Discards were dominated by fish of ages 2 to 4 .

## Recreational Fishery

Recreational statistics were collected as part of the MRFSS (Marine Recreational Fishery Statistics Survey) program. Landings (A+B1) in 2000 were 1,924,001 fish totaling 17,098,549 pounds ( 7756 mt ) (Table 1, Table 2). The landings represent an increase of 604,207 fish and an increase of $3,203,979$ pounds compared to 1999 (Table 7). The states landing the largest proportion of the recreational landings were Maryland, New Jersey, Virginia, New York, and Massachusetts (Table 6). Overall, recreational landings represented $72 \%$ by number and $65 \%$ by weight of the reported total landings, and $41 \%$ by number of total catch (landings + discard) (Figure 1). Age composition of landings were primarily ages 4 to 7 ( $74 \%$ of landings).

Recreational discards (B2's) increased in 2000 to 16,311,806 fish (Table 2, Table 7). Applying a hooking mortality rate of $8 \%$ resulted in estimated losses from hooking mortality of 1,304,944 fish (Table 2). The states with the largest proportion of the overall discards were Massachusetts, Maryland, and New York (Table 7). Recreational discards represented 28\% by number of the total catch (Figure 1, Table 2). Discards were greatest on the 1996 year class (age 4) which comprised $28 \%$ of the total.

Total recreational striped bass catch in 2000 was $3,228,945$ fish. The catch was dominated by ages 4 to 7 ( $72 \%$ of total). Total recreational discard and landings losses increased sharply between 1994 and 1997, fluctuated without a strong trend through 1999, then increased by over one million fish in 2000 (Table 10).

## Total Catch at Age

The above components are totaled by year to produce the overall catch at age matrix for VPA input (Table 11). The total catch of striped bass in 2000 was 4.68 million fish. The 2000 catch represented the highest catch since 1982, exceeding the previous high in 1997, by over 20,000 fish.

## Indices of Abundance

## Fishery Independent Indices

The Maryland gillnet survey of spawning biomass has generally declined since 1993, although there was a strong peak in 1996. The 2000 value was about one-half the series average
(Figure 2). Values for age-2 were dropped as tuning indices due to frequency of zero catches over time. The New York ocean haul seine index increased considerably for 1996-1998 and the 2000 value was about average and considerably higher than the 1999 (Figure 3). Survey values for ages 2 and 3 (lagged ahead to ages 3 and 4 ) were included this year in an attempt better estimate abundance of younger ages. The NEFSC spring inshore survey was incorporated as an ageaggregated index in the 1999 assessment, and was used in the 2000 assessment as age-specific indices. This survey increased during the early to mid-1990s before declining in 1998 and 1999. The 2000 value was one of the highest in the series (Figure 4). The Rappahannock River, Virginia pound net CPUE was used for the first time this year, in an attempt to provide more information on the overall spawning stock. This survey, begun in 1991, showed an increase with the 2000 value the series high (Figure 5). Three trawl indices, aggregated across ages, were also added for the first time in the 2000 VPA (Figure 6). The Connecticut trawl index increased steadily from 1984 to 1999, then dropped slightly in 2000. Both the Delaware and New Jersey trawl indices exhibited a sharp increase in the mid-1990s, with peaks in 1994 and 1996 for the Delaware and the New Jersey surveys, respectfully. Thereafter, both have decreased sharply.

Juvenile indices from the Chesapeake Bay (Maryland and Virginia) show improved recruitment in 2000 (Figure 7), and appeared to be fluctuating without any strong trend since the mid-1990s. Both suggested recent strong cohorts in 1993 and 1996. Juvenile indices of the Hudson and Delaware stocks showed above average recruitment in 1999 and, with the exception of the Hudson, again in 2000 (Figure 8). The NY and NJ surveys showed overall increasing trends since 1991.

The Maryland age-1 index was slightly above average in 1999 and about average in 2000, and reflected only a slight upward trend over the last few years (Figure 9). The Long Island age-1 index dropped slightly in 2000 but remained above average, while exhibiting a strong increasing trend over most of the series (Figure 9)

## Fishery Dependent Indices

The Massachusetts commercial catch per trip dropped slightly in 1999, but recovered to near-peak values in 2000 (Figure 10). The Connecticut volunteer angler catch per trip decreased in 1999 to about the 1995 and 1997 levels, and appeared to be fluctuating randomly over the last 5 years (Figure 11). No value was available for this survey for 2000. The values for age 1 (lagged
ahead as age 2) were dropped due to high PV's and low catches.
The Hudson River shad fishery bycatch of spawning striped bass (age 8+) was reconfigured by the NYDEC for use as an age-aggregate index in the VPA. This survey increased steadily through 1996, then dropped to the average for 1997-1998. The survey index dropped again in 2000 after recovering slightly in 1999 (Figure 12).

## Weight at Age

Weight at age information has not been updated since the 1996 fishery year. Therefore, weight at age from 1996 fishery data was used in the 2000 assessment for 1997 through 2000. Details of developing weights at age for 1982 to 1996 can be found in NEFSC Lab Ref. 98-03.

## Virtual Population Analysis Results

## Catch at Age

A catch at age matrix was developed using the same methods described for the 1996 assessment (NEFSC Lab Ref 98-03). Commercial landings at age were based on reported landings by state and associated age/length information. Commercial discard age data was from fishery dependent data and independent surveys using comparable gear. Recreational landings at age were based on a combination of MRFSS length samples, volunteer angler logbooks and American Littoral Society (ALS) lengths of released fish. Age composition of the recreational discards were estimated using lengths available from angler logbooks and ALS data.

The predominant age in the catch matrix was age 5, the 1995 year class, followed closely by ages 4,6 , and 7 (Table 11, Figure 13). The VPA update for the year 2000 was the first year the 1995 cohort dominated the catch, as the strong 1993 cohort dominated the catch from 1997 to 1999.

## Indicators of model fit

The ADAPT program with iterative re-weighting was used for the striped bass VPA. The model resulted in an overall mean square residual of 0.00677 , sum of squares $=7.02$ and coefficients of variation for terminal population estimates ranging from 0.17 (age 9) to 0.36 (age 1) (Table 12). Each survey used to tune the VPA contributes to the overall variance in the model, and the amount of the total variance attributable to an index is indicated by its partial variance (PV) (Table 13). Surveys or particular ages of surveys with high PV's are often deleted from
assessment runs because they contribute relatively little additional information, and such an approach has been used in the past to trim down the number of surveys.

This assessment was a compilation of several stocks and the relative importance of each component's contribution to the total harvest and population abundance was unknown. Iterative re-weighting was used to reduce the influence of surveys with high PVs while retaining the information of each survey concerning the abundance of particular stock components. Most surveys of ages 2-10 abundance had initial partial variances below 1.5, while several indices of older ages had significantly higher partial variances (Table 13). Iterative re-weighting reduces the influence of surveys with high variance by changing the weight applied to each survey, and results in all surveys providing equivalent contributions to the overall variance.

## Fishing Mortality

Average fishing mortality rate $(\mathrm{F})$ for ages 4 through 13 in 2000 was equal to 0.28 (exploitation rate (or harvest rate) of $23 \%$ ). F was fairly stable between 1997 and 2000 for the younger ages (3-8 and 4-13), but more variable for the older ages (8-13) (Table 14, Figure 14). The revised 1998 assessment average $F$ for ages 4 to 13 was 0.32 , and the 1999 assessment average F for ages 4-13 was also 0.32. After considerable changes in the catch at age and tuning indices during this assessment, the 1998 and 19994 through 13 F were essentially unchanged at 0.31 (exploitation rate of $25 \%$ ) (Table 14). The mortality on younger striped bass (ages 3-8) increased from around 0.20 in 1998 and 1999 to 0.25 in 2000. In the previous two striped bass stock assessments, mortality on older fish was estimated above the $\mathrm{F}=0.31$ target for 1998 and 1999. The 2000 assessment continued to estimate Fs greater than 0.31 on older fish for 1998 and 1999 ( 0.37 and 0.39 , respectively), but was reduced to 0.29 in 2000 . For individual cohorts, F ranged from 0.03 on age 2 to a high of 0.39 on age 10. In 2000, the 1990 through 1993 cohorts were subjected to the highest fishing mortality. The 2000 F weighted by N for ages $6-13$ was used in comparison to tag based estimates and was estimated at 0.33 .

## Partial Recruitment

Full recruitment estimated from the back-calculated partial recruitment occurred by age 7 ( $95 \%$ ). The exploitation pattern changed in 2000 to greater selectivity at younger ages (4-10) and decreased selectivity at older ages compared to previous years (Table 15). For the purpose of estimating average $F$, full recruitment was considered as age 4 , based on catch at age data.

## Population Abundance

Population abundance (stock size as of January 1, 2001) increased slightly to 45.6 million fish, following a decline in abundance from 1997 to 2000 (Table 16, Figure 15). The 2000 year class dominated the population, representing about $25 \%$ of the total abundance, while the 19982000 cohorts (ages 1-3) represented $57 \%$ of the total population (Table 16). Abundance of the 1993 cohort, which had the highest observed abundance at age 1 in the time series, remained the highest abundance for age 8 striped bass since 1982. Recruitment of age 1 fish in 2001 (2000 cohort) was estimated as 11.5 million fish, above the 1990-2000 average of 9.7 million (Figure 16). Recruitment of the 1999 cohort appeared slightly below average, while the 1998 and 1997 were about average. The 1996 year class at age 1appeared as a dominant cohort, nearly equivalent to the 1993 year class in abundance.

## Spawning Stock Biomass

Although all results are subject to uncertainty, a special caution is urged in interpreting estimates of population and spawning stock biomass. Additional uncertainty is due to the use of constant weight at age inputs since 1996 (see weight at age above) that likely bias estimates of biomass. Potential bias can be examined by comparing reported landing weights to calculated landing weights. For example, incorporating only recreational landings ( $\mathrm{A}+\mathrm{B} 1$ fish), the crossproduct of the recreational catch at age and the estimated weight at age ( $10,014 \mathrm{MT}$ ) is $30 \%$ higher than the reported landings for 2000 . The reported and calculated recreational landed weights were within $1 \%$ in 1996, but the calculated values exceeded the reported values consistently from 1997 through 2000, by 16 to 30\%. Therefore, although the VPA results (Table 17) suggest that SSB continued to increase to $20,840 \mathrm{MT}$ ( 15.9 million pounds)(Figure 17), it is quite possible that this was simply an artifact of the weights at age. Possibly, SSB peaked several years ago when total abundance peaked.

## Precision of Estimates

Uncertainty in the results of the terminal year estimate of $\mathrm{F}, \mathrm{N}$ and SSB in the VPA was evaluated using a bootstrap re-sampling algorithm. Five hundred iterations were made to obtain standard errors, coefficients of variation (CV) and bias estimates for stock size estimates of ages $1-15$ at the beginning of 2001, fishing mortality of ages 1-15 in 2000, and spawning stock biomass of females on January 1, 2001 (Table 18). Results indicate an $80 \%$ probability that F on
the fully recruited ages (ages 5-13 as listed in the input specifications) was between 0.26 and 0.35 (Figure 18). The estimate of bias was less than $5 \%$ for ages 2-15, but substantially higher for age 1. The bootstrap mean of the fully-recruited F in 1999 was 0.27 with a $2.7 \%$ bias and a CV of 0.10 .

The 2000 estimate of total abundance was between 39,046 and 55,775 with a probability of $80 \%$. The bootstrap mean was 47,143 with a bias of $4.47 \%$ (Figure 19). SSB of females was between $17,695 \mathrm{mt}$ and $22,806 \mathrm{mt}$ at an $80 \%$ probability level. However, refer to previous section for cautions in interpreting SSB results.

## Retrospective Patterns

A retrospective analysis was conducted on the VPA results with successive terminal years extending back to 1995, in order to determine trends in estimation of F or total abundance in the terminal year. The analysis revealed no consistent trend through 1996, although there was a slight tendency to under-estimate Fs in the 1995 terminal year. There was little evidence of retrospective bias between the 1999 and 2000 terminal years (Figure 20).

Relative to the current assessment, age 2+ abundance was under-estimated for the 19951997 terminal years, and slightly over-estimated for the 1998 terminal year (Figure 21).
Time Series Changes in VPA results
Since the initial VPA based assessment in 1998, changes have occurred in compiling the catch at age, choice of indices used for tuning, calculation of index values and the VPA model selection. Nevertheless, the resulting estimate of fishing mortality for ages 4 to 13 has remained relatively stable. Annual estimates of F from consecutive assessments are presented in Figure 22. Discussion

The results of the VPA for striped bass from 1982 to 2000 indicates a steady increase in total abundance until 1997 followed by a steady level through 2000. Concurrently, the catch and fishing mortality of striped bass ages 4 through 13 has increased (Figure 23). In recent years, the total removals have been dominated by the recreational sector. The increase in recreational catch in 2000 was due in part to an increase in recreational fishing effort. During 2000, the exploitation pattern also shifted to higher selectivity on younger ages although the age 4 through 13 F did not exceed target F of 0.31 .

The estimated strength of the 1996 year class increased since the last assessment. The
reason for this change appears to be the additional information provided by the recruitment of this year class to the fishery and coastal surveys. Increased catch requires that the model account for the change with increased initial abundance in the VPA population estimate. Similarly, the 1993 year class appeared to remain a dominant year class compared to previous evaluations.

The issues to be investigated in future assessments include reexamining the use of F weighted by N for comparison to tagging F estimates, the potential of a dome shaped exploitation pattern due to changes in striped bass catchability with age, implications of iterative reweighting compared to apriori weighting and the appropriateness of each of the tuning indices. In adddition, the catch weights at age will be calculated for recent years.

## Tagging Results

## Description of Tagging Programs:

The results provided here originate from nine different striped bass tagging programs conducted from Maine to North Carolina. All of these tagging programs have been in progress for eight years or longer. Producer area tagging programs operate mainly during spring, on spawning stock aggregations, utilizing a variety of capture types including pound nets, gill nets, seines and electro-shocking. Coastal tagging programs operate mainly during fall, on mixed stocks, and utilize various capture gears including hook \& line, seine, gill net, and otter trawl. For most producer area and coastal programs (as defined in the Striped Bass FMP), tagging was conducted in association with routine monitoring programs performed by the states. The Western Long Island survey uses seine gear and operates from April through November in various bays situated around the western end of Long Island, New York.

Tag release and recapture data were exchanged between the U.S. Fish and Wildlife Service (USFWS) office in Annapolis, MD, and the cooperating tagging agencies. The USFWS maintains the tag release/recovery database and provides rewards to fishermen who report the recapture of tagged fish. Through April of 2001 there were 361,674 tag releases, and 65,590 recaptures reported in the USFWS database (Tina McCrobie, personal comm.).

## Analysis Methods

The Striped Bass Tagging Committee analysis protocol is based on assumptions described in Brownie et. al. (1985). The tag recovery data is analyzed in program MARK
(White, 1999). Several important assumptions of the tagging programs taken from Brownie (1985), worth repeating here are:

1. The tagged sample is representative of the target population.
2. There is no tag loss.
3. Survival rates are not affected by the tagging itself.
4. The year of tag recoveries is correctly tabulated.

Other assumptions related to the modeling component of the analysis include;
5. The fate of each tagged fish is independent of the fate of other tagged fish.
6. The fate of a given tagged fish is a multinomial random variable.
7. All tagged individuals of an identifiable class (age, sex) in the sample have the same annual survival and recovery rates.

The program MARK calculates maximum likelihood estimates of the multinomial parameters of survival and recovery based on an observed matrix of recaptures. The analysis protocol involves the following series of steps. First, a full set of biologically reasonable candidate models are identified prior to analysis. Various patterns of survival and recovery are used to parameterize the candidate models. These include models that allow parameters to be constant, time specific, or allow time to be modeled as a continuous variable. Other models allow time periods to coincide with changes in regulatory regimes established coastwide. A list of the candidate models used in the analyses of striped bass tag recoveries and their descriptions are provided below.

| $S() r.()$. | Constant survival and reporting |
| :--- | :--- |
| $\mathrm{S}(\mathrm{t}) \mathrm{r}(\mathrm{t})$ | Time specific survival and reporting |
| $\mathrm{S}() .\mathrm{r}(\mathrm{t})$ | Constant survival and time specific reporting |
| $\mathrm{S}(\mathrm{p}) \mathrm{r}(\mathrm{t})$ | Regulatory period $*$ based survival and time specific reporting |
| $\mathrm{S}(\mathrm{p}) \mathrm{r}(\mathrm{p})$ | Regulatory period $*$ based survival and reporting |
| $\mathrm{S}() .\mathrm{r}(\mathrm{p})$ | Constant survival and regulatory period $*$ based reporting |
| $\mathrm{S}(\mathrm{t}) \mathrm{r}(\mathrm{p})$ | Time specific survival and regulatory period $*$ reporting |

| $\mathrm{S}(\mathrm{d}) \mathrm{r}(\mathrm{p})$ | Regulatory period based survival with unique terminal year and regulatory period * based reporting |
| :---: | :---: |
| $\mathrm{S}(\mathrm{v}) \mathrm{r}(\mathrm{p})$ | Regulatory period based survival with 2 terminal years unique and regulatory period * based reporting |
| $\mathrm{S}(\mathrm{Tp}) \mathrm{r}(\mathrm{Tp})$ | Linear trend within regulatory period $*$ for both survival and reporting |
| $\mathrm{S}(\mathrm{Tp}) \mathrm{r}(\mathrm{p})$ | Linear trend within regulatory period * survival and regulatory period * based reporting (no trend) |
| $\mathrm{S}(\mathrm{Tp}) \mathrm{r}(\mathrm{t})$ | Linear trend within regulatory period * survival and time specific reporting (no trend) |
| * Periods | $1=\{\geq 1987-\geq 1989\}, 2=\{\geq 1990-\geq 1994\}, 3=\{\geq 1995-2000\}$ |

These models are then fit to the tag recovery data and are arranged in order of fit by Akaike's Information Criteria (AIC) (Akaike, 1973; Burnham and Anderson, 1992). Annual survival is then calculated as a weighted average across all models, where the weight is a function of model fit (Burnham and Anderson 1998; Smith et al. 2000). The lower the AIC (ie., the better the fit), the higher the weight assigned to a specific model in the model averaging. Model averaging eliminates the need to select the single (best) model, allowing the uncertainty of model selection to be incorporated into the variance of parameter estimates (Burnham and Anderson 1998; Smith et al. 2000).

Since survival cannot be uniquely estimated for the terminal year in the fully time saturated $\{\mathrm{S}(\mathrm{t}) \mathrm{r}(\mathrm{t})\}$ model, the time saturated model is excluded from the model averaged survival estimate for the terminal year only. The final steps involve adjusting the estimates of survival for reporting rate (Kahn, 2000) and bias due to live release (Smith et al., 2000). Instantaneous fishing mortality ( F ), not directly estimated by these analysis procedures, is determined by converting survival $(S)$ to total mortality $(Z)$ and subtracting a constant value for natural mortality $(M)$ of 0.15 . As a consequence, any change in total mortality $(Z)$ results in an equal change in fishing mortality (F).

## Results

Mean instantaneous fishing mortality ( F ) from the coastal mixed stock tagging programs for striped bass tagged at twenty-eight inches and greater in total length \{believed to represent
those fish fully recruited to the coastal fisheries\} was 0.22 in 2000 (Table 19).
Stock specific instantaneous fishing mortality (F) from producer area tagging programs for striped bass twenty-eight inches and greater in total length were 0.48 for the Delaware River, 0.16 for the Maryland portion of the Chesapeake Bay, and 0.24 for the Rappahannock River, Virginia. No estimate for the Hudson River could be provided due to the low estimate of survival which, when adjusted for natural mortality, resulted in a fishing mortality estimate of zero. Therefore, the committee(s) decided to omit the Hudson tag estimate of fishing mortality from this year's assessment, as unreliable.

In the current analysis, average fishing mortality ( F ) exhibited an increasing trend over the last several years to the series high of 0.22 in 2000 for the coastal tagging programs. Producer area tagging programs exhibited similar trends in average F, rising to a series high of 0.28 in 1999. No average $F$ for producer areas was available in 2000 due to the problems identified with the Hudson River tagging analysis results.

Table 20 provides the raw estimates of survival from MARK, and components of the live release bias adjustment. The magnitude of the live release bias has decreased since the late 1980's and early 1990's, from relaxed management and the resulting effects on the proportion of tag recaptures subsequently released alive.

Table 21 provides the Akaike weights used to calculate the model averaged survival estimates for each program. Those highlighted were the highest weighted model for that program. These are provided so that the reader may evaluate the model, or models, which contributed significantly to the overall results. In nearly each case, the best fit was for those which inferred time or regulatory period specific survival or reporting. The only cases where a model of constant survival and reporting were indicated were for the New Jersey/Delaware Bay coastal program and the Virginia/Rappahannock producer area program.

Tables 22 and 23 provide the total length frequencies of tag releases by program for 2000 and the age frequency of all 2000 (year) recaptures. The length frequency data shows the relative differences within and between fish tagged on the coast and in producer area programs. The producer area programs exhibit two modes, probably related to differences in length frequency by sex. The coast programs exhibit single modes, likely related to the differences in the design of the program and the gear used in capturing fish for tagging. In general, the Massachusetts
tagging by hook and line gear tends to release proportionally more large fish than the other coast programs, whereas the North Carolina trawl survey released proportionally more small fish than other coastal tagging programs.

Age distribution of the 2000 recaptures is problematic since a few programs do not assign ages to all of the fish that are tagged. Hence, the age of individual fish cannot be inferred when those fish are recaptured at a later date. The greatest proportions of recaptures were among ages four through seven. In general, these cohorts accounted for $67 \%$ of the recaptures of fish tagged on the coast. Similarly, the greatest proportions of recaptures from producer area tag programs were from among ages four, five, and seven. These cohorts accounted for $57 \%$ of the recaptures of fish tagged in producer areas.

Table 24 provides the geographic distribution of recaptures by state and month for each of the tagging programs during 2000. The pattern of tag recoveries common to all the programs, northward movement in spring and a southward return in the fall, is reflective of the migration of fish and the pattern of fishing effort directed at striped bass.

Tables 25 through 27 provide results from the Western Long Island Survey of juvenile striped bass released from May through August. These results are reported separately because they provide survival estimates of fish tagged at very young ages ( $1,2+$ ). The time series suggests that total mortality may be higher for age 1 fish than the older (age $2+$ ) group. Trends in encounter and exploitation rates:

Annual catch rates and annual exploitation rates were estimated with tag recoveries of striped bass released by 11 agencies (1987-2000) of the Cooperative Striped Bass Tagging Program (Tables 28 to 31). The time series of annual catch rates reflects trends in fishing effort, and the time series of annual exploitation rates depicts trends in exploitation. Overall increases in annual catch rates and annual exploitation rates from 1987 to 1998 suggest an increase in fishing pressure over that part of the time series, but recent estimates of annual catch rates and annual exploitation rates have decreased for most of the 11 tagging agencies.

Estimates of annual exploitation rates of 18-28 inch fish for the recent recapture year were lower for VIMS (spring and fall releases), MDDNR (spring and fall releases), CTDEP, NCCOOP, NYDECCST, and MADFWELE, but higher than those of the previous recapture year for tagged cohorts released by DEDNREC, NJDEP, and NYDECHUD. Annual exploitation rates
for 18-28 inch fish released by coastal agencies, such as MADFWELE, NYDECCST, and NYDECHUD, have remained low across the time series, in part, because of the 28 inch length limit and a high proportion of fish released alive.

Estimates of annual exploitation rates of $>=28$ inch fish for the final recapture year were lower than those of the previous recapture year for tagged cohorts released by NCCOOP, CTDEP, MADFWELE, MDDNR (spring and fall releases), NYDECHUD, NYDECCST, and VIMS (fall releases) (exceptions included an increase in estimates for DEDNREC, and relatively no change for NJDEP). Additionally, the weighted average of exploitation rates of producer areas decreased in 2000. A weighted average of estimates from producer areas may be appropriate if recoveries occur during coastal mixing after spawning; however, many recoveries during the first year after release occur in close proximity to the producer area of release. Although the above discussion focused on changes within recent years, a better approach would be to consider trends across the entire time series. The increase in annual tag-encounter rates and annual exploitation rates from 1987-1998 may have resulted from an increase in fishing pressure, or an increase in tag reporting rates. It is unlikely that reporting rates of tagged striped bass have increased over time, although annual reporting rates have not been studied over the time series of the tagging program. The decrease in encounter and exploitation rates during recent recapture years may have resulted from a decrease in fishing effort and/or a decrease in CPUE, and indicates that fishing mortality was lower during recent years than during previous recapture years.

## Direct Enumeration Study

The jurisdictions of the Chesapeake Bay region (MD, PRFC, and VA) conduct a tagging program to estimate fishing mortality on striped bass targeted in the fall and winter fisheries within the Bay. The 2000 fishing mortality study was similar to the multiple release studies completed from 1995 through 1999. Striped bass were tagged and released in pre-set periods utilizing a multiple-release design throughout the Chesapeake Bay prior to and during the recreational fishing seasons for Maryland and Virginia. There were seven release rounds in Maryland, and three in Virginia. USFWS internal anchor tags were applied to 9,453 striped bass and the numbers of tagged fish were then adjusted for tag-induced mortality of $1.3 \%$ prior to analysis. Recoveries for the fishing mortality rate estimate were used from tagged fish harvested
by recreational/charter anglers from both jurisdictions combined in 2000.
Tag recovery and release data were analyzed with logistic regression analysis to produce a Chesapeake Bay-wide estimate of F for the recreational, charter and commercial components of the 2000 striped bass fishery. Estimates of the rate of exploitation (U) were directly derived from modeling of tag recovery data from fish harvested by recreational anglers and were determined for the recreational/charter season component of the fishery, bay-wide. Estimates of exploitation for the recreational/charter season were converted to instantaneous rates $\left(\mathrm{F}_{\mathrm{R}}\right)$. These estimates were adjusted to include the resident portion of the commercial and recreational fisheries that occurred during summer 2000, winter 2000-2001 and during spring/summer of 2001, respectively. The expanded estimates of $F_{T}$ were calculated based on weighting of recreational/charter estimates of $F_{R}$ by proportional additions of spring recreational or commercial harvest in numbers. Estimated nonharvest mortality ( 0.10 ) was added to the point estimate of $\mathrm{F}_{\mathrm{T}}=0.18$ to obtain the final estimate of bay-wide fishing mortality of $\mathrm{F}_{\text {Bay }}=0.28$ for the 2000 fishing season. The variance of 0.0012 is equivalent to a CV of $19.5 \%$.

## Discussion

As with any modeling exercise, there are several sources of uncertainty associated with these methods for estimation of survival and recovery parameters in the tagging analysis for striped bass. The primary source involves the violation of general assumptions, as mentioned earlier in this text. Measures of uncertainty specific to the striped bass tagging study involve adhoc methods employed to correct for live release bias, as well as the use of a contemporary reporting rate to adjust retrospective recaptures. Finally, the application of a constant value for natural mortality across all groups and time does not allow for differences in natural mortality with size of fish or time.

In addition, caution is urged when comparing the tag based fishing mortality estimates over time due to the many changes that occurred in the tagging program analysis. For example, the committee switched to computer program MARK from PC Surviv, and began incorporating the live release bias adjustment. Further changes have occurred to the bias adjustment calculations from last year. The committee is applying $8 \%$ mortality to the live releases, appropriate since most of the recaptures released alive are reported from hook and line gear, which was not incorporated into last years estimates. Also, the reporting rate was re-calculated
using strictly recreational recaptures, which resulted in a lower reporting rate of 0.433 from the rate used previously (0.55) (D.Kahn, personal comm.).

Resolution of many of these issues will take time, and may require a change in the analysis protocol adopted by the tagging committee. It is likely that additional research is required to investigate the differences in release mortality associated with different capture gears, or that the committee may need to investigate other formulae to directly determine instantaneous fishing mortality (F), for example. Some solutions may take longer, as the state of the theoretical science is generally in advance of any practical application.

## Conclusion

The results of the striped bass stock assessment for 1982-2000 indicate that the overall abundance of the stock is very high and the fishing mortality remains below the target fishing mortality. The abundance increased steadily between 1982 and 1997 but has remained stable since.

The VPA results indicate fishing mortality increased steadily until 1999 but decreased slightly in 2000. There was a noticeable shift in the exploitation pattern in the 2000 fishery. In previous years, striped bass in older age classes experienced the highest proportion of mortality while the recent assessment showed a proportional shift to younger age groups. This was likely the result of changes in management policies that were enacted during 2000 intended to reduce mortality of older fish to levels approaching target F .

Fishing mortality calculated using the catch at age model and the tagging model produced comparable trends but different absolute values. The average F based on tags was 0.22 whereas the comparable VPA F (average weighted by N for ages $6-13$ ) was 0.33 . Among fish greater than 28 inches from individual stocks, the Delaware stock experienced the highest mortality based followed by the mixed stock estimate from coastal New York. In contrast, the Maryland mortality estimate was 0.16 and the coastal Massachusetts estimate of 0.08 .

Overall, the Atlantic stocks of striped bass appear to be abundant in number, capable of producing strong incoming year classes and are being fished at levels within the bounds of the current Fishery Management Plan.
