## Northeast Fisheries Science Center Reference Documents

This series is a secondary scientific series designed to assure the long-term documentation and to enable the timely transmission of research results by Center and/or non-Center researchers, where such results bear upon the research mission of the Center (see the outside back cover for the mission statement). These documents receive internal scientific review, and most receive copy editing. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these documents.

Editorial Treatment: To distribute this report quickly, it has not undergone the normal technical and copy editing by the Northeast Fisheries Science Center's (NEFSC's) Editorial Office as have most other issues in the NOAA Center Reference Document NMFS-NE series. Other than the four covers and first two preliminary pages, all writing and editing have been performed by - and all credit for such writing and editing rightfully belongs to - those so listed on the title page.

If you do not have Internet access, you may obtain a paper copy of a document by contacting the senior Center author of the desired document. Refer to the title page of the document for the senior Center author's name and mailing address. If there is no Center author, or if there is corporate (i.e., non-individualized) authorship, then contact the Center's Woods Hole Laboratory Library (166 Water St., Woods Hole, MA 02543-1026).

Information Quality Act Compliance: In accordance with section 515 of Public Law 106554, the Northeast Fisheries Science Center completed both technical and policy reviews for this report. These predissemination reviews are on file at the NEFSC Editorial Office.

This document may be cited as:

## TABLE OF CONTENTS

Foreword ..... 4
A. STOCK ASSESSMENT OF SUMMER FLOUNDER FOR 2018
Terms of Reference ..... 15
Executive Summary by Term of Reference (TOR) ..... 17
Working Group and Meeting Attendees ..... 24
Stock Unit ..... 26
Management Summary ..... 26
Assessment History ..... 28
TOR A1. Estimate catch from all sources including landings and discards. Describe the spatial and temporal distribution of landings, discards, and fishing effort. Characterize the uncertainty in these sources of data. Compare previous recreational data to re-estimated Marine Recreational Information Program (MRIP) data (if available) ..... 32
TOR A2. Present survey data available, and describe the basis for inclusion or exclusion ofthose data in the assessment (e.g., indices of relative or absolute abundance, recruitment, statesurveys, age-length data). Investigate the utility of commercial or recreational LPUE as ameasure of relative abundance. Characterize uncertainty and any bias in these data41
TOR A3. Describe life history characteristics and the stock's spatial distribution (juveniles andadults), including any changes over time. Describe factors related to productivity of the stock andany ecosystem factors influencing recruitment. If possible, integrate results into the stockassessment55
TOR A4. Estimate annual fishing mortality, recruitment and stock biomass (total and spawningstock) for the time series, and estimate their uncertainty. Include retrospective analyses(historical and within-model) to allow a comparison with previous assessment results andprojections, and to examine model fit. Examine sensitivity of model results to changes in re-estimated recreational data70
TOR A5. State the existing stock status definitions for "overfished" and "overfishing". Thenupdate or redefine biological reference points (BRPs; point estimates or proxies for BMSY,$\mathrm{B}_{\text {Threshold, }}$ F MSy and MSY) and provide estimates of their uncertainty. If analytic model-basedestimates are unavailable, consider recommending alternative measurable proxies for BRPs.Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, oralternative) BRPs93
TOR A6. Make a recommendation about what stock status appears to be, based on the existingmodel (i.e., model from previous peer reviewed accepted assessment) and with respect to a newmodeling approach(-es) developed for this peer review100
TOR A7. Develop approaches and apply them to conduct stock projections ..... 102
TOR A8. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in most recent SARC reviewed assessment and review panel reports and MAFMC SSC reports. Identify new research recommendations ..... 104
References ..... 110
Tables ..... 121
Figures ..... 245
Appendix A1: In-meeting Analyses for the SARC ..... 452
B. STOCK ASSESSMENT OF STRIPED BASS FOR 2018
Contributors ..... 457
Terms of Reference ..... 458
Executive Summary by Term of Reference (TOR) ..... 459
Management and Assessment History ..... 465
TOR B1: Investigate all fisheries independent and fisheries dependent data sets, including life history, indices of abundance, and tagging data. Discuss strengths and weaknesses of the data sources ..... 471
TOR B2: Estimate commercial and recreational landings and discards. Characterize the uncertainty in the data and spatial distribution of the fisheries. Review new MRIP estimates of catch, effort and the calibration method, if available ..... 498
TOR B3: Use an age-based model to estimate annual fishing mortality, recruitment, totalabundance and stock biomass (total and spawning stock) for the time series and estimate theiruncertainty. Provide retrospective analysis of the model results and historical retrospective.Provide estimates of exploitation by stock component and sex, where possible, and for total stockcomplex512
TOR B4: Use tagging data to estimate mortality and abundance, and provide suggestions for further development ..... 544
TOR B5: Update Biological Reference Points and determine stock status ..... 557
TOR B6: Provide annual projections of catch and biomass under alternative harvest scenarios.Projections should estimate and report annual probabilities of exceeding threshold BRPs for Fand probabilities of falling below threshold BRPs for biomass566
TOR B7: Review and evaluate the status of the Technical Committee research recommendations listed in the most recent SARC report. Identify new research recommendations. Recommend timing and frequency of future assessment updates and benchmark assessments ..... 569
References ..... 572
Tables ..... 585
Figures ..... 735
List of appendices ..... 870
Appendix B1: Growth, sex ratios, and maximum ages by state and through years ..... 871
Appendix B2: Update to the Female Striped Bass Maturity Schedule ..... 889
Appendix B3: Development of Age-specific Natural Mortality Rates for Striped Bass ..... 910
Appendix B4: Report of the Striped Bass VPA Indices Workshop ..... 916
Appendix B5: Atlantic Striped Bass Commercial and Recreational Monitoring and Development of Removals at Age ..... 934
Appendix B6: Supplemental Commercial Discard Materials ..... 954
Appendix B7: Tag Recovery Estimates of Migration of Striped Bass from Chesapeake and Delaware Bays ..... 960
Appendix B8: ADMB Code for the Striped Bass Two-Stock Statistical Catch-At-Age (2SCA) Model ..... 983
Appendix B9: Diagnostic Plots from the 2SCA Model for Atlantic Striped Bass ..... 1058
Appendix B10: Model Structure, Parameterization, Diagnostic Plots, and Output for the Non- Migration SCA Model for Atlantic Striped Bass ..... 1092
Appendix B11: Supplemental Tagging Model Materials ..... 1134
Appendix B12: Projections from the non-migration model ..... 1163
Appendix B13: Additional analysis for striped bass requested at SARC 66 ..... 1170

## Foreword

The Northeast Regional Stock Assessment Workshop (SAW) process has three parts: preparation of stock assessments by the SAW Working Groups and/or by ASMFC Technical Committees / Assessment Committees; peer review of the assessments by a panel of outside experts who judge the adequacy of the assessment as a basis for providing scientific advice to managers; and a presentation of the results and reports to the Region's fishery management bodies.
Starting with SAW-39 (June 2004), the process was revised in two fundamental ways. First, the Stock Assessment Review Committee (SARC) became smaller panel with panelists provided by the Independent System for Peer Review (Center of Independent Experts, CIE). Second, the SARC provides little management advice. Instead, Council and Commission teams (e.g., Plan Development Teams, Monitoring and Technical Committees, Science and Statistical Committee) formulate management advice, after an assessment has been accepted by the SARC. Starting with SAW-45 (June 2007) the SARC chairs were from external agencies, but not from the CIE. Starting with SAW-48 (June 2009), SARC chairs are from the Fishery Management Council's Science and Statistical Committee (SSC), and not from the CIE. Also at this time, some assessment Terms of Reference were revised to provide additional science support to the SSCs, as the SSC's are required to make annual ABC recommendations to the fishery management councils.

Reports that are produced following SAW/SARC meetings include: An Assessment Summary Report - a summary of the assessment results in a format useful to managers; an Assessment Report - a detailed account of the assessments for each stock;
and the SARC panelist reports - a summary of the reviewer's opinions and recommendations as well as individual reports from each panelist. SAW/SARC assessment reports are available online at
http://www.nefsc.noaa.gov/nefsc/publication s/series/crdlist.htm. The CIE review reports and assessment reports can be found at http://www.nefsc.noaa.gov/nefsc/saw/".
The 66th SARC was convened in Woods Hole at the Northeast Fisheries Science Center, November 27-30, 2018 to review benchmark stock assessments of Summer flounder and Striped bass. CIE reviews for SARC66 were based on detailed reports produced by NEFSC Assessment Working Groups. This Introduction contains a brief summary of the SARC comments, a list of SARC panelists, the meeting agenda, and a list of attendees (Tables $1-3$ ). Maps of the Atlantic coast of the USA and Canada are also provided (Figures 1-5).

## Outcome of Stock Assessment Review Meeting:

Text in this section is based on SARC-66
Review Panel reports (available at http://www.nefsc.noaa.gov/nefsc/saw/ under the heading "SARC-66 Panelist Reports").

SARC-66 concluded that the summer flounder stock is neither overfished nor did it experience overfishing in 2017. The Panel concluded that the SAW WG had reasonably and satisfactorily completed its tasks. Estimates of recreational catch came from newly calibrated MRIP time-series that reflected a revision of both the intercept and effort surveys. The Bigelow indices take account of trawl efficiency estimates at length from 'sweep-study' experiments. No factor was identified as strongly influencing
the spatial shift in spawner biomass or the level of recruitment. The assessment shows that current mortality from all sources is greater than recent recruitment inputs to the stock, which has resulted in a declining stock trend.

SARC-66 concluded that the striped bass stock is overfished and experienced overfishing in 2017. The SARC Panel accepted the single stock, non-migration SCA model for management, and concluded that all ToRs were met for that model. In addition, the Panel reviewed a new two stock model developed by the SAW WG. This model represents an innovative advance and the SARC panel recommends continued development and refinement for possible use in the future.

Table 2. 66th Stock Assessment Workshop/Stock Assessment Review Committee (SAW/SARC) Benchmark stock assessment for A. Summer flounder and B. Striped bass

November 27-30, 2018

Stephen H. Clark Conference Room - Northeast Fisheries Science Center Woods Hole, Massachusetts

AGENDA* (version: Nov. 20, 2018)

| 3:30-3:45 PM | Public Comments |  |
| :---: | :---: | :---: |
| 3:45-4 PM | Break |  |
| 4-6 PM | Revisit with Presenters (A. Summer flounder) Robert Latour, SARC Chair | Brian Linton |
| 7 PM | (Social Gathering) |  |
| Thursday, Nov. 29 |  |  |
| 8:30-10:30 | Revisit with Presenters (B. Striped bass) | Alicia Miller |
| 10:30-10:45 | Break |  |
| 10:45-12:15 | Review/Edit Assessment Summary Report (A. Summer flounder) |  |
|  | Robert Latour, SARC Chair | Chris Legault |
| 12:15-1:15 PM | Lunch |  |
| 1:15-2:45 PM | (cont.) Edit Assessment Summary Report (A. Summer flounder) |  |
|  | Robert Latour, SARC Chair | Chris Legault |
| 2:45-3 PM | Break |  |
| 3-6 PM | Review/edit Assessment Summary Report (B. Striped bass) |  |
|  | Robert Latour, SARC Chair | Chris Legault |

## Friday, Nov. 30

9:00 AM - 5:00 PM

SARC Report writing
*All times are approximate, and may be changed at the discretion of the SARC chair. The meeting is open to the public; however, during the Report Writing sessions we ask that the public refrain from engaging in discussion with the SARC.

## A: SUMMER FLOUNDER STOCK ASSESSMENT FOR 2018

Terms of Reference

1. Estimate catch from all sources, including landings and discards. Describe the spatial and temporal distribution of landings, discards, and fishing effort. Characterize the uncertainty in these sources of data. Compare previous recreational data to re-estimated Marine Recreational Information Program (MRIP) data (if available).
2. Present the survey data available, and describe the basis for inclusion or exclusion of those data in the assessment (e.g., indices of relative or absolute abundance, recruitment, state surveys, age-length data, etc.). Investigate the utility of commercial or recreational LPUE as a measure of relative abundance. Characterize the uncertainty and any bias in these sources of data.
3. Describe life history characteristics and the stock's spatial distribution (for both juveniles and adults), including any changes over time. Describe factors related to productivity of the stock and any ecosystem factors influencing recruitment. If possible, integrate the results into the stock assessment.
4. Estimate annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series, and estimate their uncertainty. Include retrospective analyses (both historical and within-model) to allow a comparison with previous assessment results and projections, and to examine model fit. Examine sensitivity of model results to changes in re-estimated recreational data.
5. State the existing stock status definitions for "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; point estimates or proxies for $\mathrm{B}_{\mathrm{MSY}}$, $\mathrm{B}_{\text {Threshold, }} \mathrm{F}_{\text {msy }}$ and MSY) and provide estimates of their uncertainty. If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs.
6. Make a recommendation ${ }^{\mathbf{a}}$ about what stock status appears to be, based on the existing model (i.e., model from previous peer reviewed accepted assessment) and with respect to a new modeling approach(-es) developed for this peer review.
a. Update the existing model with new data and make a stock status recommendation (about overfished and overfishing) with respect to the existing BRP estimates.
b. Then use the newly proposed modeling approach(-es) and make a stock status recommendation with respect to "new" BRPs and their estimates (from TOR-5).
c. Include descriptions of stock status based on simple indicators/metrics (e.g., ageand size-structure, temporal trends in population size or recruitment indices, etc).
7. Develop approaches and apply them to conduct stock projections.
a. Provide numerical annual projections (5 years) and the statistical distribution (i.e., probability density function) of the catch at $\mathrm{F}_{\text {MSY }}$ or an $\mathrm{F}_{\text {MSY }}$ proxy (i.e. the overfishing level, OFL) (see Appendix to the SAW TORs). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F, and probabilities of falling below threshold BRPs for biomass. Use a
A. Summer Flounder
sensitivity analysis approach in which a range of assumptions about the most important uncertainties in the assessment are considered (e.g., terminal year abundance, variability in recruitment).
b. Comment on which projections seem most realistic. Consider the major uncertainties in the assessment as well as sensitivity of the projections to various assumptions. Identify reasonable projection parameters (recruitment, weight-atage, retrospective adjustments, etc.) to use when setting specifications.
c. Describe this stock's vulnerability (see "Appendix to the SAW TORs") to becoming overfished, and how this could affect the choice of ABC.
8. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in most recent SARC reviewed assessment and review panel reports and MAFMC SSC reports. Identify new research recommendations.
${ }^{\text {a NOAA }}$ Fisheries has final responsibility for making the stock status determination for this stock based on best available scientific information.

## EXECUTIVE SUMMARY

TOR1. Estimate catch from all sources, including landings and discards. Describe the spatial and temporal distribution of landings, discards, and fishing effort. Characterize the uncertainty in these sources of data. Compare previous recreational data to re-estimated Marine Recreational Information Program (MRIP) data (if available).

Total U.S. commercial landings of summer flounder from Maine to North Carolina peaked in 1979 at 17,945 mt (39.561 million lb). The reported landings in 2017 of 2,644 mt $=5.829$ million lb were about $3 \%$ over the final 2017 commercial quota of $2,567 \mathrm{mt}=5.659$ million lb . The commercial landings in 2017 were the lowest since 1943. Commercial discards in 2017 were estimated at $906 \mathrm{mt}=1.997$ million lb .

Summary landings statistics for the summer flounder recreational fishery (catch type $A+B 1$ ) were estimated by the National Marine Fisheries Service (NMFS) Marine Recreational Fishery Statistics Survey (MRFSS 1982-2003) and Marine Recreational Information Program (MRIP 2004-2017). Estimated 2017 landings in the recreational fishery (as estimated by the 'Old' MRIP) were $1,447 \mathrm{mt}=3.190$ million lb , about $85 \%$ of the recreational harvest limit ( $1,711 \mathrm{mt}$ $=3.772$ million lb). The recreational landings in 2017 were the lowest since 1989. Recreational discards were estimated at $442 \mathrm{mt}=0.974$ million lb.

In July 2018, the MRIP replaced the existing estimates of recreational catch ('Old' MRIP) with a calibrated 1982-2017 time series that corresponds to new survey methods that were fully implemented in 2018 ('New’ MRIP). For comparison with the existing estimates noted above, the 2018 MRIP calibrated estimate of 2017 recreational landings is $4,565 \mathrm{mt}=10.064$ million lb , 3.2 times the old estimate. The 2018 MRIP calibrated estimate of 2017 recreational discards is $1,496 \mathrm{mt}=3.298$ million lb , 3.4 times the old estimate.

The calibrated recreational catch estimates ('New’ MRIP) increased the 1982-2017 total catch by an average of $29 \%$ (from $13,308 \mathrm{mt}=29.339$ million lb to $17,216 \mathrm{mt}=37.955$ million lb ), ranging from $+11 \%$ in 1989 to $+43 \%$ in 2017. The 2018 SAW-66 stock assessment model includes the 2018 MRIP calibrated estimates of recreational landings and discards.

Catch data from both recreational and commercial fisheries Vessel Trip Reports (VTRs) as well as observer reports were summarized to determine spatial trends in catch and effort in the fishery in recent decades. A northerly trend of offshore commercial catches (and by inference, effort) has developed during the present decade with the largest catches now south of Rhode Island. Commercial catches of summer flounder at its southern extent are reduced after 2005. The fishery observer data show a larger presence of large summer flounder catches on Georges Bank after 2005. Recreational fishing catch distribution (and by inference, effort) from party and charter boats is relatively unchanged throughout the 1990s and 2000s.

TOR2. Present the survey data available, and describe the basis for inclusion or exclusion of those data in the assessment (e.g., indices of relative or absolute abundance, recruitment, state surveys, age-length data, etc.). Investigate the utility of commercial or recreational LPUE as a
measure of relative abundance. Characterize the uncertainty and any bias in these sources of data.

Research survey indices of abundance are available from the NEFSC, MADMF, RIDFW, CTDEEP, NYDEC, NJDFW, DEDFW, MDDNR, VIMS, VIMS ChesMMAP, VIMS NEAMAP, and NCDMF surveys. All available fishery independent research surveys were used in population model calibration. For the NEFSC trawl survey indices, the years sampled by the FSV HB Bigelow (2009-2017) are treated as a separate series from the earlier years (1982-2008) that were sampled by the FSV Albatross IV. The Bigelow indices incorporate trawl efficiency estimates at length from 'sweep-study' experiments and are expressed as absolute abundances.

The SFWG evaluated the utility of the fishery dependent landings- and catch-per unit effort based indices as measures of abundance in the summer flounder stock assessment. The SFWG concluded that the calculation of directed effort in the fishery dependent data is problematic. For the commercial data, the effort information is dependent on the accurate recording by the fishermen themselves, but since the collection of this data is not a focus of their operation the recording the fishing time or length of tow may not be completely accurate and could affect the calculation of the CPUE index. There is a lack of consistency in the reporting requirements for parts of the commercial VTR time series. For the MRIP recreational data, the calculation of directed effort is even more problematic, as there are a number of different ways to define summer flounder trips. Further, there is variation in the number of rods and reels (gear quantity) and the time of fishing for each trip. The unit of catch is also inconsistently reported in the forhire recreational VTRs. In total, these elements make the calculation of effort challenging when working with fishery dependent data time series. The SFWG noted that over the long term, and especially since fishery quotas were instituted in the early 1990s, there have been a number of regulatory changes differing in timing and magnitude for each state (e.g., seasonal closures, seasonal trip/possession limits, and minimum size limits). This information is not part of the commercial and recreational catch databases and so must be developed independently and integrated within the generalized model used for index standardization. This information could not be modeled adequately as covariates or classification variables within the generalized model framework (i.e., inability to develop a model which converges and produces valid parameter estimates) for the commercial fishery data. The modeling difficulties call into question the utility of both the nominal and model-based fishery dependent CPUE as indices of summer flounder abundance. The SFWG felt the standardization procedure was still subject to an unknown, likely negative, bias. In addition, the SFWG felt the multiple fishery-independent surveys available to this assessment had sufficient spatial coverage, such that inclusion of the fishery-dependent indices was not necessary, as might be the case for an assessment that lacked adequate fishery independent sampling. Based on these concerns, the SFWG recommended that the fishery dependent standardized indices of abundance not be used in the summer flounder assessment model.

TOR3. Describe life history characteristics and the stock's spatial distribution (for both juveniles and adults), including any changes over time. Describe factors related to productivity of the stock and any ecosystem factors influencing recruitment. If possible, integrate the results into the stock assessment.

The NEFSC survey data show trends in the most recent years of decreasing mean length and weight at age in all seasons and for both sexes, a trend in von Bertalanffy parameters that indicates 'slower growth' (smaller observed and predicted length and weight at age), and a trend of delayed maturity. There are no trends in length-weight relationship parameters or condition factor that suggest a trend of reduced 'condition' for summer flounder. There are trends in sex ratio that indicate a decreasing proportion of females (and therefore an increasing proportion of males) for ages 2 and older. These trends in life-history characteristics had an important effect on the values of the biological reference points updated in this assessment.

There are apparent changes in spatial distribution of summer flounder over the last four decades with a general shift northward and eastward. Spatial expansion is more apparent in the years of greater abundance since about 2000, although it has continued even with the most recent declines in biomass. Higher levels of exploitation can lead to reduced heterogeneity in age structure, particularly a reduction in the abundance of older age fish. However, work examining recent shifts in recruits and an examination of other ecosystem factors suggests other mechanisms may also be contributing factors.

The impact of the change in distribution and weight-at-age on summer flounder stock productivity is important but difficult to determine. Although recruitment has been relatively low in recent years, the driver of these low recruitment events has not been identified, as attempts to link specific covariates to changes in the spatial distribution of recruits did not uncover a clear driving variable. Many factors may be impacting the productivity of the stock, and identifying the mechanisms driving these observed changes is challenging and warrants further research. The use of recent weights-at-age and maturity-at-age in the biological reference point estimates (TOR 5) and in catch projections (TOR 7) attempts to capture the effects of these factors on the future productivity of the stock.

TOR4. Estimate annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series, and estimate their uncertainty. Include retrospective analyses (both historical and within-model) to allow a comparison with previous assessment results and projections, and to examine model fit. Examine sensitivity of model results to changes in reestimated recreational data.

Fishing mortality rates and stock sizes were estimated using the ASAP statistical catch at age model. An age-specific instantaneous natural mortality rate providing an average $M=0.25$ was assumed for all years. Fishing mortality on the fully selected age 4 fish ranged between 0.744 and 1.622 during 1982-1996 and then decreased to 0.245 in 2007. Since 2007 the fishing mortality rate has increased and was 0.334 in 2017. The $90 \%$ confidence interval for $F$ in 2017 was 0.276 to 0.380. Spawning stock biomass (SSB) decreased from 30,451 mt in 1982 to 7,408 mt in 1989 and then increased to 69,153 mt in 2003. SSB has decreased since 2003 and was estimated to be 44,552 in 2017. The 90\% confidence interval for SSB in 2017 was 39,195 to 50,935 mt. The 1983 year class is the largest in the assessment time series at 102 million fish, while the 1988 year class is the smallest at only 12 million fish. The average recruitment from 1982 to 2017 is 53 million fish at age 0. Recruitment has been below average since 2011, ranging from 30 to 42 million and averaging 36 million fish. The survival of summer flounder recruits, expressed as the R/SSB ratio, was higher in the 1980s and early 1990s than in the years since 1996.

An 'internal' retrospective analysis was conducted to examine the stability of the model estimates as data were removed from the last years of the time series. Retrospective runs were made for terminal years back to 2010. The summer flounder stock assessment has historically exhibited a retrospective pattern of underestimation of F and overestimation of SSB; the causes of this previous pattern have not been determined. In the current assessment model, however, no persistent retrospective patterns are evident. 'Historical' retrospectives indicate that general trends of fishing mortality, stock biomass, and recruitment have been consistent since the 1990s assessments. The use of the new calibrated estimates of recreational landings and discards in the current assessment increased the 1982-2017 total catch by an average of almost 30\%. While the magnitude of fishing mortality was not strongly affected, the increased catch has resulted in increased estimates of stock size compared to the historical assessments.

TOR5. State the existing stock status definitions for "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; point estimates or proxies for $\mathrm{B}_{\mathrm{MSY}}$, $B_{\text {Threshold, }}$ F msy and MSY) and provide estimates of their uncertainty. If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs.

The existing 2013 SAW 57 biological reference points for summer flounder are based on stochastic yield and SSB per recruit and stochastic projection models using values from the 2013 assessment. The fishing mortality reference point is $F 35 \%=0.309(C V=15 \%)$ as a proxy for FMSY. The biomass reference point proxy is estimated as the projection of Jan 1, 2013 stock sizes at $F 35 \%=0.309$ and mean recruitment of 43 million fish per year (1982-2012). The SSBMSY proxy is estimated to be 62,394 mt (137.6 million lb; CV = 13\%), and the biomass threshold of one-half SSBMSY is estimated to be $31,197 \mathrm{mt}$ ( 68.8 million lb ; CV = 13\%). The MSY proxy is estimated to be $12,945 \mathrm{mt}$ (28.539 million lb; CV = 13\%).

The new 2018 SAW-66 biological reference points for summer flounder are similarly based on stochastic yield and SSB per recruit and stochastic projection models. The new fishing mortality reference point is $F 35 \%=0.448(C V=15 \%)$ as a proxy for FMSY. The biomass reference point proxy is estimated as the projection of Jan 1, 2018 stock sizes at $F 35 \%=0.448$ and mean recruitment of 53 million fish per year (1982-2017). The SSBMSY proxy is estimated to be 57,159 mt (126.0 million lb; CV = 15\%), and the biomass threshold of one-half SSBMSY is estimated to be 28,580 mt ( 63.0 million lb; CV = 15\%). The MSY proxy is estimated to be $15,973 \mathrm{mt}$ ( 35.214 million $\mathrm{lb} ; C V=15 \%$ ).

The increase in the F reference point (and MSY) but decrease in the biomass reference point is due primarily to the effect of decreased mean weight at age for older ages (mainly ages 6 and $7+$, because of increasing numbers of older fish available in fishery and survey samples and increasing number of males [which are smaller and of lower mean weight] present in the catch and survey samples at those ages), and secondarily to a more domed-shaped average fishery selectivity pattern. These combined factors result in 'flatter’ (i.e., lower slope through F35\%) SSB per recruit at F and percent MSP at F curves in the current assessment when compared to the previous 2013 SAW57 benchmark.

TOR6. Make a recommendation ${ }^{\text {a }}$ about what stock status appears to be, based on the existing model (i.e., model from previous peer reviewed accepted assessment) and with respect to a new modeling approach(-es) developed for this peer review.
a. Update the existing model with new data and make a stock status recommendation (about overfished and overfishing) with respect to the existing BRP estimates.
b. Then use the newly proposed modeling approach(-es) and make a stock status recommendation with respect to "new" BRPs and their estimates (from TOR-5).
c. Include descriptions of stock status based on simple indicators/metrics (e.g., age- and sizestructure, temporal trends in population size or recruitment indices, etc).
a) A model with data through 2017, but with the same configuration and settings as the old (existing) 2013 SAW 57 model, provides estimates appropriate to compare with the old (existing) reference points, which are the fishing mortality threshold FMSY proxy $=F 35 \%=0.309$ and biomass target SSBMSY proxy $=$ SSBMSY35\% $=62,394 \mathrm{mt}$, with biomass threshold $1 / 2$ SSBMSY35\% $=31,197 \mathrm{mt}$. The existing model indicates that $F$ in $2017=0.244$ and SSB in $2017=34,350 \mathrm{mt}$, so the stock was not overfished and overfishing was not occurring.
b) The final model adopted by the 2018 SAW-66 SFWG for the evaluation of stock status indicates the summer flounder stock was not overfished and overfishing was not occurring in 2017 relative to the new biological reference points established in this 2018 SAW-66 assessment. The fishing mortality rate was estimated to be 0.334 in 2017, below the new fishing mortality threshold reference point $=F M S Y=F 35 \%=0.448$. SSB was estimated to be 44,552 mt in 2017, $78 \%$ of the new biomass target reference point $=S S B M S Y=S S B 35 \%=57,159 \mathrm{mt}$, and $56 \%$ above the new biomass threshold with $1 / 2$ SSBMSY $=1 / 2$ SSB35\% $=28,580 \mathrm{mt}$.
c) The age structure of the total catch and NEFSC trawl surveys has expanded since the late 1990s when few fish were caught over age-4 and catch rates were relative low. Most aggregate survey indices showed increasing trends from the late 1990s through the mid-2000s. These metrics indicate that the reduction in fishing mortality that occurred through the $F$ reduction/stock rebuilding plan kept total mortality from all sources $(M+F)$ low enough to allow the abundance as indicated by the surveys to increase and the age-structure to expand. However, since the mid-2000s, most aggregate survey indices of abundance and/or biomass have remained stable or declined. This decline suggests the total mortality is too high to maintain an increasing stock trend. The exact cause of the observed trend is difficult to determine. Although recruitment indices have been below average in the most recent years, the driver of this pattern has not been identified nor is it clear if this pattern will persist in the future. There are also observed declines in the mean weights-at-age for both sexes and the age of maturity for age-1 fish, but no observed changes in the length-weight relationship or fish condition indices (Fulton's K). The observed shift in spatial distribution northward and eastward along shelf has continued since the mid2000s, during a time of both abundance increase and during the recent declines. Other sources of unaccounted for mortality or changes in fishing pressure or exploitation patterns could be contributing factors. Regardless of cause, declines in survey indices suggest that current mortality from all sources is greater than current recruitment inputs to the stock. If recruitment improves, current catches may allow the stock to increase, but if recruitment remains low or decreases further, then reductions in catch will be necessary.

TOR7. Develop approaches and apply them to conduct stock projections.
a. Provide numerical annual projections (5 years) and the statistical distribution (i.e., probability density function) of the catch at $\mathrm{F}_{\text {MSY }}$ or an $\mathrm{F}_{\text {MSY }}$ proxy (i.e. the overfishing level, OFL) (see Appendix to the SAW TORs). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F , and probabilities of falling below threshold BRPs for biomass. Use a sensitivity analysis approach in which a range of assumptions about the most important uncertainties in the assessment are considered (e.g., terminal year abundance, variability in recruitment).
b. Comment on which projections seem most realistic. Consider the major uncertainties in the assessment as well as sensitivity of the projections to various assumptions. Identify reasonable projection parameters (recruitment, weight-at-age, retrospective adjustments, etc.) to use when setting specifications.
c. Describe this stock's vulnerability (see "Appendix to the SAW TORs") to becoming overfished, and how this could affect the choice of ABC.
a) Stochastic projections were made to provide forecasts of stock size and catches in 2019-2023 consistent with the new (updated) 2018 SAW-66 biological reference points. The recommended projections assume that recent (2013-2017) patterns of fishery selectivity, discarding, maturity at age and mean weight at age will continue over the time span of the projections. The projections assume that $100 \%$ of the 2018 ABC (5,999 mt = 13.226 million lb) will be caught. The recommended OFL projections use F2019-F2023 = fishing mortality threshold FMSY proxy = $F 35 \%=0.448$ and sample from the estimated recruitment for 1982-2017. The recommended OFL catches are 14,208 mt in 2019 (CV = 12\%), 14,040 mt in 2020 (CV = 11\%), 14,411 mt in 2021 (CV = 11\%), 14,912 in 2022 (CV=13\%), and 15,335 in 2023 (CV=15\%). For the projections at fixed FMSY proxy $=F 35 \%=0.448$, there is $0 \%$ probability of exceeding the fishing mortality threshold and 0\% probability of falling below the biomass threshold during 2019-2023.
b, c) The projection results presented have a realistic probability of being achieved, and the summer flounder stock has a low vulnerability to becoming overfished, given recent trends in stock productivity and the management regime in place.

TOR8. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in most recent SARC reviewed assessment and review panel reports and MAFMC SSC reports. Identify new research recommendations.

Research recommendations have been subset as 8.1) from the previous 2013 SAW 57 benchmark assessment, 8.2) from the 2013-2018 MAFMC SSC reports, and 8.3) new recommendations from the 2018 SAW-66 review.

## WORKING GROUP PROCESS

The Stock Assessment Workshop (SAW) Summer Flounder Working Group (SFWG) met during January 30-February 1, May 29-31, and September 17-20, 2018 to develop the benchmark stock assessment of summer flounder (fluke) through 2017. The following scientists and managers constituted the 2018 SFWG:

Jeff Brust
Jessica Coakley
Tiffany Cunningham
Chris Legault
Jason McNamee

Tim Miller
Charles Perretti
Patrick Sullivan
Mark Terceiro

New Jersey Division of Fish and Wildlife (NJDFW)
Mid-Atlantic Fishery Management Council (MAFMC);
SFWG Chair
Massachusetts Division of Marine Fisheries (MADFW)
National Marine Fisheries Service (NMFS)
Northeast Fisheries Science Center (NEFSC)
Rhode Island Division of Fish and Wildlife (RIDFW),
Atlantic States Marine Fisheries Commission (ASMFC)
Technical Committee Chair
NMFS NEFSC
NMFS NEFSC
Cornell University
NMFS NEFSC; Assessment Lead

In addition to the SFWG, the following scientists and managers attended these meetings:

| Charles Adams | NMFS NEFSC |
| :--- | :--- |
| Ariele Baker | NMFS NEFSC |
| Jessica Blaylock | NMFS NEFSC |
| Russ Brown | NMFS NEFSC |
| Steve Cadrin | University of Massachusetts-Dartmouth-SMAST; SCeMFiS |
| Matthew Cunningham | NMFS NEFSC |
| Kiley Dancy | MAFMC |
| Kevin Friedland | NMFS NEFSC |
| Emerson Hasbrouck | Cornell University |
| Andy Jones | NMFS NEFSC |
| Jeff Kipp | Atlantic States Marine Fisheries Commission (ASMFC) |
| Joe Langan | University of Rhode Island |
| Scott Large | NMFS NEFSC |
| Brian Linton | NMFS NEFSC |
| Andy Lipsky | NMFS NEFSC |
| John Maniscalco | New York Department of Environmental Conservation |
|  | (NYDEC) |
| Mark Maunder | Inter-American Tropical Tuna Commission (IATTC) |
| Alicia Miller | NMFS NEFSC |
| Paul Nitchske | NMFS NEFSC |
| Mike Palmer | NMFS NEFSC |
| Eric Powell | University of Southern Mississippi; SCeMFiS |

Kirby Rootes-Murdy
Gary Shepherd

## STOCK UNIT

The definition provided by Wilk et al. (1980) of a unit stock extending from Cape Hatteras north to New England has been accepted in this and previous assessments. A consideration of summer flounder stock structure incorporating tagging data concluded that most evidence supported the existence of stocks north and south of Cape Hatteras, with the stock north of Cape Hatteras possibly composed of two distinct spawning aggregations, off New Jersey and Virginia-North Carolina (Kraus and Musick 2001). The current assessment stock unit is consistent with the conclusions of Kraus and Musick (2001). The Mid-Atlantic Fishery Management Council (MAFMC) and Atlantic States Marine Fisheries Commission (ASMFC) joint Fishery Management Plan (FMP) defines the management unit for summer flounder as extending from the southern border of North Carolina north to the U.S.-Canadian border. The management unit is consistent with the conclusions a summer flounder genetics study that revealed no population subdivision at Cape Hatteras (Jones and Quattro 1999).

As part of the 2013 SAW 57 assessment (NEFSC 2013), Kajajian et al. (2013 MS) evaluated whether otolith chemistry could be used to determine if there are chemical differences in juvenile otoliths that can subsequently be used as a natural tag to discern summer flounder nursery habitats and quantify stock structure and movement along the U.S. east coast. They used state natural resource agency and university collections of juvenile summer flounder ( $\mathrm{n}=138$ ) collected in fall 2011 with bottom trawls from estuarine habitats along the US East Coast: Long Island Sound, Delaware Bay, Chesapeake Bay, Pamlico Sound, and the coastal inshore waters of South Carolina and Georgia. They noted that in fish that are not bilaterally symmetrical, such as summer flounder, the left and right sagittal otoliths often exhibit divergent growth patterns and mass and may have differences in chemical composition. Prior to the analysis of area-scale differences in juvenile otolith signatures, they investigated the assumption of sagittal equivalence. Kajajian et al. ( 2013 MS) found there were significant mass and overall otolith chemistry differences between the left and right sagittae, originating from $\delta^{13} \mathrm{C}, \delta^{18} \mathrm{O}, \mathrm{Li}, \mathrm{Mg}$, and Sr. Left sagittae were used to compare area-scale differences, and Kajajian et al. (2013 MS) found strong differences between the nurseries: Delaware Bay, Chesapeake Bay, North Carolina, and the South-Atlantic Bight provided sufficient samples for analysis. All studied elements were significantly different between areas, thus they used the 'all-possible combinations' approach to uncover the models that produced the highest classification success, finding that a five-variable model using $\delta^{13} \mathrm{C}, \delta^{18} \mathrm{O}$, Li, Mg, and Sr produced the highest classification accuracy at $93 \%$ with the fewest variables. Kajajian et al. ( 2013 MS ) concluded that, due to the lack of equivalence within the sagittal pair, the choice of otolith impacted subsequent analyses in the summer flounder, and that otolith chemistry can be used successfully to investigate summer flounder population structure and connectivity.

## MANAGEMENT SUMMARY

Summer flounder are jointly managed by the MAFMC and the ASMFC. The MAFMC and ASMFC cooperatively develop fishery regulations, with the National Marine Fisheries Service (NMFS) serving as the federal implementation and enforcement entity within the United States (U.S.) Department of Commerce. Cooperative management was developed because significant catch is taken from both state (0-3 miles offshore) and federal waters (>3-200 miles
offshore).
The MAFMC is one of eight regional fishery management councils created when the U.S. Congress passed the Magnuson-Stevens Fishery Conservation and Management Act of 1976 (MSA). The law created a system of regional fisheries management designed to allow for regional, participatory governance. The MAFMC develops fishery management plans and recommends management measures to the Secretary of Commerce through the NMFS for federal fisheries in the Exclusive Economic Zone (EEZ) of the U.S.

The ASMFC is an interstate fisheries commission created by an interstate compact ratified by the 15 U.S. Atlantic coast states and approved by the U.S. Congress in 1942. The ASMFC coordinates the management of 27 species within state waters and is guided by two pieces of legislation: the Atlantic Striped Bass Conservation Act of 1984 and the Atlantic Coastal Fisheries Cooperative Management Act of 1993. As result of these Acts, all Atlantic coast states that are included in an ASMFC fishery management plan must implement required conservation provisions of the plan or the Secretary of Commerce may impose a moratorium for fishing in the noncompliant state's waters.

Cooperative management of the summer flounder fishery began through the implementation of the original joint Summer Flounder Fishery Management Plan (FMP) in 1988, a time that coincided with the lowest levels of stock biomass for summer flounder since the late 1960s. In 1993, Amendment 2 to the FMP enacted the bulk of the fishery management program, including regulations designed to meet fishing mortality rate targets. The FMP measures included an annual fishery landings limit with 60\% allocated to the commercial fishery and 40\% to the recreational fishery based on the historical (1980-1989) division of landings, with the commercial allocation further distributed among the states (Maine through North Carolina) based on their share of commercial landings during 1980-1989. In addition, Amendment 2 established: 1) a commercial minimum landed fish size limit of 13 in ( 33 cm ), 2) a minimum mesh size of 5.5 in ( 140 mm ) diamond or 6.0 in ( 152 mm ) square for commercial vessels using otter trawls that possess $100 \mathrm{lb}(45 \mathrm{~kg}$ ) or more of summer flounder, with exemptions for the flynet fishery and vessels fishing in an exempted area off southern New England during 1 November to 30 April, 3) moratoria on commercial summer flounder permits and associated qualifying criteria, 4) reporting requirements for the commercial and for-hire recreational fisheries, and 5) annually adjustable regulations for the recreational fishery, including an annual harvest limit, closed seasons, a 14 in ( 36 cm ) minimum landed fish size, and possession limits.

A timeline of major summer flounder management actions is summarized in the table below. Most of the Amendment 2 management measures are still in place at present, with some modifications and additions as described below. Additional management actions and all FMP documents can be viewed at http://www.mafmc.org/fisheries/fmp/sf-s-bsb and http://www.asmfc.org/species/summer-flounder.

| Year | Document | Management Action |
| :---: | :---: | :---: |
| 1988 | Original FMP | Established original joint management plan for summer flounder <br> Established a 13 -inch ( 33 cm ) total length minimum size requirement (commercial and recreational) <br> Implemented permit requirements for the commercial and recreational fisheries |
| 1990 | Amendment 1 | Established an overfishing definition for summer flounder |
| 1993 | Amendment 2 | Established rebuilding schedule <br> Established annual commercial quotas (allocated by state) and recreational harvest limits <br> Established a moratorium permits and qualifying criteria for commercial fishery <br> Established minimum mesh size requirements for trawl vessels (5.5" diamond or 6.0 " square in codend) <br> Implemented monthly logbook requirements for commercial and for-hire recreational fisheries; required mandatory weekly dealer reporting (effective Jan. 1, 1994) <br> Established annually adjustable possession limits, size limits, and open seasons for the recreational fishery, including a 14 inch ( 36 cm ) recreational minimum size limit |
| 1993 | Amendment 3 | Increased the possession threshold triggering mesh requirements to $200 \mathrm{lb}(91 \mathrm{~kg})$ from November 1-April 30 |
| 1995 | Amendment 7 | Revised the F reduction schedule for summer flounder |
| 1997 | Amendment 10 | Modified commercial minimum mesh size requirements: 5.5" diamond or 6.0 " square required throughout net (previously required only in codend) <br> Continued moratorium on commercial summer flounder permits |
| 1999 | Amendment 12 | Brought FMP into compliance with revised MSA National Standards, including revising the overfishing definition for summer flounder |
| 1997 | 1997 fishery specifications | Raised the commercial minimum fish size to 14 inches ( 36 cm ) total length |
| 2001 | Framework 2 | Established state-specific recreational management option for summer flounder ("conservation equivalency") |
| 2004 | Framework 5 | Established option for multi-year specification of quota (up to three years at a time) |
| 2007 | Framework 7 | Built flexibility into process to define and update stock status determination criteria as needed through assessment process |
| 2011 | Amendment 15 | Established Annual Catch Limits (ACLs) and Accountability Measures (AMs) consistent with the 2007 reauthorization of the Magnuson-Stevens Act |

## ASSESSMENT HISTORY

Amendment 1 to the FMP in 1990 established the overfishing definition for summer flounder as equal to Fmax, initially estimated as Fmax $=0.23$ (NEFC 1990). Amendment 2 in 1992 established target fishing mortality rates for summer flounder for 1993-1995 as $\mathrm{F}=0.53$, and Fmax $=0.23$ for 1996 and beyond. The results of stock assessments conducted in the mid-

1990s indicated that summer flounder abundance was not increasing as rapidly as projected when Amendment 2 regulations were implemented. In anticipation of the need to reduce fishery quotas in 1996 to meet the management target of Fmax, the MAFMC and ASMFC modified the fishing mortality rate reduction schedule in 1995 to allow for more stable landings between years while slowing the rate of stock rebuilding. Amendment 7 to the FMP set target fishing mortality rates of $\mathrm{F}=0.41$ for 1996 and $\mathrm{F}=0.30$ for 1997, with a target of $\mathrm{Fmax}=0.23$ for 1998 and beyond. Total landings were to be capped at 8,400 mt (18.519 million lbs) in 1996-1997 unless a higher quota in those years provided a realized $\mathrm{F}=0.23$.

Amendment 12 in 1999 defined overfishing for summer flounder as occurring when the fishing mortality rate exceeded the threshold fishing mortality rate of FMSY. Because FMSY could not be reliably estimated for summer flounder, Fmax $=0.24$ was used as a proxy for FMSY. FMSY was also defined as the target fishing mortality rate. Under Amendment 12, the stock was defined to be overfished when total stock biomass fell below the biomass threshold of one-half of the biomass target, BMSY. Because BMSY could not be reliably estimated, the biomass target was defined as the product of total biomass per recruit and contemporary (19821996) median recruitment, at that time estimated to be $153,350 \mathrm{mt}$ ( 338 million lbs), with the biomass threshold defined as $76,650 \mathrm{mt}$ ( 169 million lbs). In the 1999 stock assessment (Terceiro 1999) the reference points were updated using new estimates of median recruitment (1982-1998) and mean weights at age (1997-1998), which resulted in a biomass target of $106,444 \mathrm{mt}$ ( 235 million lbs) and biomass threshold of $53,222 \mathrm{mt}$ ( 118 million lbs). The Terceiro (1999) reference points were retained in the 2000 and 2001 stock assessments (NEFSC 2000, MAFMC 2001a) because of the stability of the input data. Concurrent with the development of the 2001 assessment, the MAFMC and ASMFC convened the Summer Flounder Overfishing Definition Review Committee to review these biological reference points. The work of this Committee was later reviewed by the MAFMC Scientific and Statistical Committee (SSC) in August 2001. The SSC recommended that using the FMSY proxy for Fmax $=0.26$ was appropriate and should be retained for 2002, and endorsed the recommendation of SARC 31 (NEFSC 2000) which stated that "...the use of Fmax as a proxy for FMSY should be reconsidered as more information on the dynamics of growth in relation to biomass and the shape of the stock recruitment function become available" (MAFMC 2001b).

The 2002 SAW 35 assessment (NEFSC 2002a) indicated the summer flounder stock was overfished and overfishing was occurring relative to the biological reference points. The fishing mortality rate had declined from 1.32 in 1994 to 0.27 in 2001, marginally above the threshold fishing mortality of Fmax $=0.26$. Total stock biomass in 2001 was estimated at $42,900 \mathrm{mt}$ ( 94.578 million lbs), or $19 \%$ below the biomass threshold ( $53,200 \mathrm{mt}$; 117.286 million lbs). The 2002 SAW35 Review Panel concluded that updating the biological reference points was not warranted at that time (NEFSC 2002a). Subsequent updates to the stock assessment were completed in 2003 (Terceiro 2003a) and 2005 (NEFSC 2005). While the 2003 assessment found the summer flounder stock was not overfished and no overfishing was occurring, the 2005 assessment found the stock again experiencing overfishing. The 2005 SAW 41 assessment provided updated values for the fishing mortality and stock biomass reference points (NEFSC 2005).

A peer review of the assessment occurred in 2006 by the NMFS Office of Science and Technology (S\&T) (Terceiro 2006a, 2006b). This review made several recommendations, including modification of the definition of the overfished stock from the original definition under Amendment 2 to the FMP. Instead of using January 1 total stock biomass (TSB), the stock was
considered overfished when November 1 spawning stock biomass (SSB) fell below one-half SSBMSY $=44,706 \mathrm{mt}$ ( 98.6 million lbs). Further, the threshold fishing mortality was revised to be Fmax $=0.28$. The 2006 S\&T assessment concluded that the stock was not overfished, but that overfishing was occurring relative to the updated reference points (Terceiro 2006b).

The 2007 assessment update (SFWG 2007) found that relative to the 2006 S\&T assessment biological reference points, the stock was overfished and overfishing was occurring. The fishing mortality rate estimated for 2006 was 0.35 , a significant decline from the 1.32 estimated for 1994 but still above the threshold of 0.28 .

A peer review of the assessment occurred at the 2008 SAW 47 (NEFSC 2008a). In the 2008 SAW 47 assessment, the age-structured assessment model changed from a Virtual Population Analysis (VPA) model to an Age Structured Assessment Program (ASAP) statistical catch at age model (Legault and Restrepo 1998), with the fishery catch was modeled as two fleets, totals landings and total discards. A new value for the instantaneous natural mortality rate (M) was adopted, changing from a constant value of $M=0.20$ to age- and sex-specific values that resulted in a mean value of $\mathrm{M}=0.25$. Biological reference points were therefore also revised; the proxy for FMSY = Fthreshold changed from Fmax to F35\%. The assessment concluded that the stock was not overfished and overfishing was not occurring in 2007, relative to the revised biological reference points. The fishing mortality rate was estimated to be 0.288 in 2007, below the threshold fishing mortality reference point FMSY $=\mathrm{F} 35 \%=0.310$. SSB was estimated to be 43,363 mt ( 95.599 million lbs) in 2007, about $72 \%$ of the biomass target reference point of SSBMSY = SSB35\% = 60,074 mt (132.441 million lbs). The assessment exhibited a consistent retrospective pattern of underestimation of F and overestimation of SSB, but no consistent retrospective pattern in recruitment. The 2006 SAW 47 benchmark assessment was subsequently updated in 2009-2012 (Terceiro 2009, 2010, 2011, 2012) with comparable results. The 2011 update indicated that the stock had been rebuilt to the SSB target reference point in 2010.

The most recent peer review of the assessment occurred at the 2013 SAW 57 (NEFSC 2013). The ASAP assessment model and proxy reference points were the same as used in the 2008 SAW 47 and subsequent 2009-2012 updates. The benchmark assessment concluded that the stock was not overfished and overfishing was not occurring in 2012 relative to the updated biological reference points. Fishing mortality on the fully selected age 4 fish ranged between 0.790 and 1.745 during 1982-1996. The fishing mortality rate has decreased from 0.849 in 1997 to 0.285 in 2012, below the updated threshold fishing mortality reference point FMSY $=\mathrm{F} 35 \%=$ 0.309. Spawning stock biomass (SSB) decreased from 24,300 mt in 1982 to 5,521 mt in 1989, and then increased to a peak of 53,156 mt by 2010. SSB was estimated to be 51,238 mt in 2012, about $82 \%$ of the new biomass target reference point SSBMSY $=$ SSB35\% $=62,394 \mathrm{mt}$. While the assessment had historically exhibited a consistent retrospective pattern of underestimation of F and overestimation of SSB, no persistent internal retrospective patterns were evident in the 2013 benchmark. The historical retrospective indicates that general trends of fishing mortality, stock biomass, and recruitment have been consistent since the 1990s assessments. The 2013 SAW 57 benchmark assessment was subsequently updated in 2015 and 2016 (Terceiro 2015, 2016) with comparable results.

The last assessment update in 2016 (Terceiro 2016) indicated that the stock was not overfished but overfishing was occurring in 2015 relative to the biological reference points from the 2013 SAW 57 benchmark assessment. Since 2007 the fishing mortality rate had increased and was 0.390 in 2015, 26\% above the 2013 SAW 57 threshold fishing mortality FMSY = F35\% =
0.309. Spawning stock biomass (SSB) had decreased since 2010 and was estimated to be 36,240 mt in 2015, 58\% of the 2013 SAW 57 target biomass SSBMSY = SSB35\% = 62,394 mt, and 16\% above the 2013 SAW 57 threshold biomass $1 / 2$ SSBMSY $=1 / 2$ SSB35\% $=31,197 \mathrm{mt}$. Recruitment was estimated to have been below average since 2010. By 2016, the consistent pattern in the underestimation of F and the overestimation of SSB noted in earlier assessments had returned. Moderate internal model retrospective patterns in F and SSB were evident in the 2016 assessment model, as the average retrospective errors over the last 7 terminal years were $-20 \%$ and $+11 \%$, about twice as large as the magnitude of the 2013 SAW 57 retrospective errors. The model estimates of 2015 F and SSB adjusted for this internal retrospective error were still within the model estimate $90 \%$ confidence intervals, however, and so no adjustment of the terminal year estimates was been made for stock status determination or projections. There continued to be consistent retrospective pattern in recruitment averaging $+22 \%$. The historical assessment retrospective likewise indicated the emergence of a gradual upward adjustment of recent F estimates and downward adjustment of recent SSB estimates.

TOR A1. Estimate catch from all sources including landings and discards. Describe the spatial and temporal distribution of landings, discards, and fishing effort. Characterize the uncertainty in these sources of data. Compare previous recreational data to re-estimated Marine Recreational Information Program (MRIP) data (if available).

## COMMERCIAL FISHERY LANDINGS

Total U.S. commercial landings of summer flounder from Maine to North Carolina peaked in 1979 at 17,945 mt ( 39.561 million lb, Table A1, Figure A1). The reported landings in 2017 of $2,644 \mathrm{mt}=5.829$ million lb were about $3 \%$ over the final 2017 commercial quota of $2,567 \mathrm{mt}=5.659$ million lb . The commercial landings in 2017 were the lowest since 1943.

Since 1980, about 70\% of the commercial landings of summer flounder have come from the Exclusive Economic Zone (EEZ; greater than 3 miles from shore). Large variability in summer flounder landings exist among the states, over time, and the percent of total summer flounder landings taken from the EEZ has varied widely among the states. The commercial landings are assumed to be reported with minimal error. The uncertainty of the reported landings due to assignment to statistical area equates to a Coefficient of Variation (CV) of $0.2 \%$.

## Northeast Region (NER; Maine to Virginia)

Annual commercial landings data for summer flounder in years prior to 1994 were obtained from detailed trip-level landings records contained in master data files maintained by the Northeast Fisheries Science Center (NEFSC; the "weighout system" of 1963-1993) and from summary reports of the Bureau of Commercial Fisheries and its predecessor the U.S. Fish Commission (1940-1962). Prior to 1994, summer flounder commercial landings were allocated to NEFSC 3-digit statistical area according to interview data (Burns et al. 1983). Beginning in 1994, landings estimates were derived from mandatory dealer reports under the current NMFS Northeast Region (NER) summer flounder quota monitoring system. Beginning in 1994, the dealer landings have been allocated to statistical area using fishing dealer and fishing Vessel Trip Reports (VTR) in a multi-tiered allocation procedure at the fishing-trip level (Wigley et al., 2007). Three-digit statistical areas 537-539 (Southern New England), 611-616 (New York Bight), 621, 622, 625, and 626 (Delmarva region), and 631 and 632 (Norfolk Canyon area) have generally accounted for over 80\% of the NER commercial landings since 1994.

A summary of length and age sampling of summer flounder landings collected by the NEFSC commercial fishery port agent system in the NER is presented in Table A2. For comparability with the manner in which length frequency sampling in the recreational fishery has been evaluated, sampling intensity is expressed in terms of metric tons ( mt ) of landings per 100 fish lengths measured. The sampling is proportionally stratified by market category (jumbo, large, medium, small, and unclassified), with the sampling distribution generally reflecting the distribution of commercial landings by market category. Overall sampling intensity has improved since 1995, from 165 mt per 100 lengths to less than 40 mt per 100 lengths since 2005, and temporal and geographic coverage has generally improved as well.

The age composition of the NER commercial landings for 1982-1999 was generally estimated semi-annually by market category (small, medium, large, jumbo, and unclassified) and 1-digit statistical area (e.g., area 5 or area 6), using standard NEFSC procedures (market category
length frequency samples converted to mean weights by length-weight relationships; mean weights in turn divided into landings to calculate numbers landed by market category; market category numbers at length apportioned to age by application of age-length keys). For 20002002, sampling was generally sufficient to make quarterly estimates of the age composition in area 6 for the large and medium market categories. Since 2003, sampling has generally been sufficient to make quarterly estimates of the age composition in areas 5 and 6 for the medium, large, and jumbo market categories. The proportion of large and jumbo market category fish (generally of ages 3 and older) in the NER landings has increased since 1996, while the proportion of small market category landings (generally of ages 0 and 1 ) has become very low (Table A3).

For this benchmark assessment, the 1982-2017 NER commercial landings at age were recompiled to ensure use of the most recent data and consistent application of standard procedures. The resulting changes in the landings at age in total were relatively minor, ranging from a decrease in total landed numbers of $9 \%$ in 1983 and 1990 to an increase of $8 \%$ in 1989, with an overall time series increase of $4 \%$. The change over the last 5 years averaged less than $-0.1 \%$. The mean size of fish landed in the NER commercial fishery has been increasing since 1994, and has averaged about 1.0 kg ( 2.2 lb ) since 2013, typical of an age 4 summer flounder (Table A4).

## North Carolina

The North Carolina winter trawl fishery accounts for about 99\% of summer flounder commercial landings in North Carolina. A separate landings at age matrix for this component of the commercial fishery was developed from North Carolina Division of Marine Fisheries (NCDMF) length and age frequency sample data. The NCDMF program samples about $10 \%$ of the winter trawl fishery landings annually, most recently at rates of less than 10 metric tons of landings per 100 lengths measured (Table A5). All length frequency data used in construction of the North Carolina winter trawl fishery landings at age matrix were collected in the NCDMF program; age-length keys from NEFSC commercial data and NEFSC spring survey data (19821987) and NCDMF commercial fishery data (1988 and later) were combined by appropriate statistical area and semi-annual period to resolve lengths to age. Fishery regulations in North Carolina also changed between 1987 and 1988, with increases in both the minimum mesh size of the codend and minimum landed fish size taking effect. It is not clear whether the change in regulations or the change in keys, or some combination, is responsible for the decreases in the numbers of age- 0 and age- 1 fish estimated in the North Carolina commercial fishery landings since 1987. Landed numbers at age and mean weight at age from this fishery are shown in Tables A6-A7.

## COMMERCIAL FISHERY DISCARDS

## The Standardized Bycatch Reporting Method (SBRM)

The Standardized Bycatch Reporting Methodology (SBRM) Omnibus Amendment to the fishery management plans of the Northeast region was implemented in February 2008 to address the requirements of the MSA to include standardized bycatch reporting methodology in all FMPs of the New England and Mid-Atlantic Fishery Management Councils. The Standardized Bycatch Reporting Method (SBRM) for the estimation of discards (Wigley et al. 2008, 2011) has now
been adopted for most NER stock assessments that have been subject to a benchmark review since 2009. In the SBRM, the sampling unit is an individual fishing trip. For summer flounder, trips were partitioned into fleets using four classification variables: calendar quarter, regional area fished, gear type, and mesh size. Calendar quarter was based on the landed date of the fishing trip, and was used to capture seasonal variations in both fishing activity and discard rates. Area fished was based on statistical reporting area; trips where area fished was not recorded or was otherwise unknown were excluded. Two regional areas were defined: New England (NE) comprising statistical reporting areas in the ‘ 500 ’ series (which includes Southern New England, Georges Bank, and the Gulf of Maine), and Mid-Atlantic (MA) comprising statistical areas in the '600’ series. Live discards were estimated using a combined D/K ratio estimator (Cochran 1963) where $\mathrm{D}=$ discard pounds of a given species, and $\mathrm{K}=$ the kept pounds of all species landed in each trip as reported by Dealer records. Total discards (in weight) by fleet were derived by multiplying the estimated discard rate in that fleet by the corresponding fleet landings from the Dealer reports. Further computational and statistical details are provided in Wigley et al. (2011).

Estimates were developed by calendar quarter, gear (fish trawl, scallop dredge, gillnet, pot, and hand/longline gear), and mesh strata (extra-large $=>8$ inch; 8 in $>$ large $=>5.5$ inch; small < 5.5 inch codend). For this assessment, new stratum for hand/longline, pots, and gillnet gear were included (all under 'gillnet' in tables). The new fishery stratum increased the estimates of live discard by 30 mt , or about $2 \%$, over the time series. Overall, live commercial discards averaged 1,396 $\mathrm{mt}(\mathrm{CV}=35 \%)$ over the time series, ranging from $274 \mathrm{mt}(\mathrm{CV}=58 \%)$ in 1991 to 2,689 mt (CV = 39\%) in 1992 (Table A8).

## Commercial Discard Estimates at age

Observer length frequency samples were converted to sample numbers at age and sample weight at age frequencies by application of NEFSC survey length-weight relationships and observer, commercial fishery, and survey age-length keys. Sample weight proportions at age were next applied to the raised fishery discard estimates to derive fishery total discard weight at age. Fishery discard weights at age were then divided by fishery observed mean weights at age to derive fishery discard numbers at age. Classification to age for 1989-1993 was done by semiannual periods using observer age-length keys, except for 1989, when first period lengths were aged using combined commercial landings (quarters 1 and 2 ) and NEFSC spring survey age-length keys. Since 1994, only NEFSC survey age-length keys were used, since observer agelength keys were not yet available and commercial landings age-length keys contained an insufficient number of small summer flounder ( $<40 \mathrm{~cm}=16$ inches) that account for much of the discards. For comparability with the manner in which length frequency sampling in the recreational fishery has been evaluated, sampling intensity is expressed in terms of metric tons (mt) of live discards per 100 fish lengths measured. The sampling has been stratified by gear type (fish trawl, scallop dredge, and gillnet/other) since 1994. Overall sampling intensity has improved since 1999, from 152 mt per 100 lengths to less than 20 mt per 100 lengths since 2004 (Table A9).

The reasons for discarding in the fish trawl, scallop dredge, and gillnet/pot/handline fisheries have been changing over time. During 1989 to 1995, the minimum size regulation was recorded as the reason for discarding summer flounder in over $90 \%$ of the observed trawl and scallop dredge tows. In 1999, the minimum size regulation was provided as the reason for discarding in $61 \%$ of the observed trawl tows, with quota or trip limits given as the discard
reason in $26 \%$ of those tows, and high-grading in $11 \%$. In the scallop fishery in 1999, quota or trip limits was given as the discard reason in over $90 \%$ of the observed tows. During 2000-2005, minimum size regulations were identified as the discard reason in 40-45\% of the observed trawl tows, quota or trip limits in $25-30 \%$ of those tows, and high grading in $3-8 \%$. In the scallop fishery during 2000-2005, quota or trip limits was given as the discard reason for over $99 \%$ of the observed tows. During 2006-2017, minimum size regulations were identified as the discard reason in $15-20 \%$ of the observed trawl tows, quota or trip limits in 60-70\%, and high grading in $5-10 \%$. In the scallop fishery during 2006-2017, quota or trip limits was given as the discard reason for about $40 \%$ of the observed tows, with about $50 \%$ reported as "unknown." For the entire time series, quota or trip limits was given as the reason for discarding in over $90 \%$ of the gillnet/pot/handline hauls. As a result of the increasing impact of trip limits, fishery closures, and high grading as reasons for discarding, the age structure of the summer flounder discards has also changed over time, with a higher proportion of older fish being discarded since about 2002 (Table A10).

As recommended by SAW 16 (NEFSC 1993), a commercial fishery discard mortality rate of $80 \%$ was applied to develop the final estimate of discard mortality from live discard estimates. The SAW 47 and SAW 57 assessments (NEFSC 2008a, 2013) considered information from 2007 and 2009 Cornell University Cooperative Extension studies (Hasbrouck et al 2011, 2012). These studies conducted scientific trips on summer inshore and winter offshore multispecies commercial trawling vessels to determine discard mortality rates relative to tow duration, fish size, and the amount of time fish were on the deck of the vessel. The mean inshore mortality was $78.7 \%$, while the mean offshore mortality was $80.4 \%$; both estimates are very close to the estimated overall discard mortality of $80 \%$ used in the assessment. Another study (Yergey et al. 2012) conducted by Rutgers University using acoustic telemetry to evaluate both on-deck and latent discard mortality found total discard mortality in the trawl fishery to be $81.7 \%$, again very close to the estimated overall discard mortality of $80 \%$ used in the assessment. The $80 \%$ discard mortality rate assumption is reflected in the estimates of commercial fishery discards at age and mean weights at age in Tables A10-A11.

## RECREATIONAL FISHERY CATCH

## Recreational Fishery Landings

Summary landings statistics for the summer flounder recreational fishery (catch type A+B1) as estimated by the NMFS Marine Recreational Fishery Statistics Survey (MRFSS 19822003) and Marine Recreational Information Program (MRIP 2004-2017) are presented in Table A12. Estimated 2017 landings in the recreational fishery were $1,447 \mathrm{mt}=3.190$ million lb, about $85 \%$ of the recreational harvest limit ( $1,711 \mathrm{mt}=3.772$ million lb). The recreational landings in 2017 were the lowest since 1989.

Length frequency sampling intensity for the recreational fishery was calculated by MRFSS sub-regions (North - Maine to Connecticut; Mid - New York to Virginia; South - North Carolina) based on a metric tons of landings per hundred lengths measured basis (Burns et al. 1983; Table A13). To convert the recreational fishery length frequencies to age, MRFSS sample length frequency data and NEFSC commercial and survey age-length data were examined in terms of number of fish measured/aged on various temporal and geographical bases. Correspondences were made between MRFSS intercept date (quarter), commercial quarter, and
survey season (spring and summer/fall), and between MRFSS sub-region, commercial statistical areas, and survey depth strata to integrate data from the different sources. Based on the number, size range, and distribution of lengths and ages, a semi-annual, sub-regional basis of aggregation was adopted for matching of commercial and survey age-length keys with recreational length frequency distributions to convert lengths to ages. Limited MRFSS length sampling for larger fish resulted in a high degree of variability in mean length for older fish, especially at ages 5 and older during the first decade of the time series. Attempts to estimate length-weight relationships from the MRFSS biological sampling data provided unsatisfactory results. As a result, the commercial fishery quarterly length (mm) to weight (g) relationships from Lux and Porter (1966) were used to calculate annual mean weights at age from the estimated age-length frequency distribution of the landings.

The recreational landings historically were dominated by relatively young fish. During 1982-1996, age 1 fish accounted for over $50 \%$ of the landings by number and fish of ages 0 to 3 accounted for over $95 \%$ of landings by number. No fish from the recreational landings were determined to be older than age 7. With increases in the minimum landed size since 1996 (to 14.5 in [ 37 cm ] in 1997, 15 in [ 38 cm ] in 1998-1999, generally 15.5 in [39 cm] in 2000, and various state minimum sizes from 14.0 [ 36 cm ] to 21 in [ 53 cm ] in 2001-2017) and a trend to lower fishing mortality rates, the age composition of the recreational landings now includes mainly fish at ages 3 and older, at mean weights of greater than 1 kg per fish (Tables A14-A15).

## Recreational Fishery Discards

To account for all removals from the summer flounder stock by the recreational fishery, some assumptions about the biological characteristics and discard mortality rate of the recreational live discard need to be made. Biological samples of the MRFSS/MRIP catch type B2 fish were not routinely taken before 2005. In previous assessments, data available from NYDEC surveys (1988-1992) of New York party boats suggested that nearly all (>95\%) of the fish released alive from boats were below the minimum regulated size (during 1988-1992, 14 in [ 36 cm ] in New York state waters), that nearly all of these fish were age 0 and age 1 summer flounder, and that these age 0 and 1 summer flounder occurred in about the same proportions in the live discard as in the landings. It was therefore assumed that all B2 catch would be of lengths below regulated size limits, and be either age 0 or age 1 in all three sub-regions during 19821996. Catch type B2 was allocated on a semi-annual, sub-regional basis in the same ratio as the annual age 0 to age 1 proportion observed in the landings during 1982-1996. Mean weights at age were assumed to be the same as in the landings during 1982-1996.

The minimum landed size in federal and most state waters increased to 14.5 in ( 37 cm ) in 1997, to 15.0 in ( 38 cm ) in 1998-1999, and to 15.5 in ( 39 cm ) in 2000. Applying the same logic used to allocate the 1982-1996 recreational released catch to size and age categories during 1997-2000 implied that the recreational fishery released catch included fish of ages 2 and 3. Investigation of data from the CTDEEP Volunteer Angler Survey (VAS) for 1997-1999 and from the American Littoral Society (ALS) for 1999, and comparing the length frequency of released fish in these programs with the MRFSS data on the length frequency of landed fish below the minimum size, indicated this assumption was valid for 1997-1999 (MAFMC 2001a). The CTDEEP VAS and ALS data, along with data from the NYDEC Party Boat Survey (PBS), was used to validate this assumption for 2000. For 1997-2000 all B2 catch was assumed to be of lengths below regulated size limits, and therefore comprised of ages 0 to 3. Catch type B2 was
allocated on a sub-regional basis in the same ratio as the annual age 0 to age 3 proportions observed in the landings at lengths less than 37 cm in 1997, 38 cm in 1998-1999, and 39 cm in 2000.

In 2001, many states adopted different combinations of minimum size and possession limits to meet management requirements. Examination of data provided by MD sport fishing clubs, the CTDEEP VAS, the Virginia Marine Resources Commission (VAMRC) VAS, the ALS, and the NYDEC PBS indicated that the assumption that fish released are those smaller than the minimum size remained valid since 2001, and so catch type B2 was characterized by the same proportion at length as the landed catch less than the minimum size in the respective states. The differential minimum size by state has continued since 2001, and increased samples of the recreational fishery discards by state agency Volunteer Angler Surveys, the MRFSS/MRIP For Hire Survey (FHS), and the American Littoral Society has allowed direct characterization the length frequencies of the discards from sample data and presumably a more accurate estimate of the discard in weight.

Studies conducted to estimate recreational fishery discard mortality for striped bass and black sea bass suggest a rate of 8\% for striped bass (Diodati and Richards 1996) and 5\% for black sea bass (Bugley and Shepherd, 1991). Work by the states of Washington and Oregon with Pacific halibut (a potentially much larger flatfish species, but otherwise morphologically similar to summer flounder) found "average hooking mortality...between eight and 24 percent" (IPHC 1988). An unpublished tagging study by the NYDEC (Weber 1984 MS) on the survival of released sublegal summer flounder caught by hook-and-line suggested a total, non-fishing mortality rate of $53 \%$, which included discard plus tagging mortality as well as deaths by natural mortality. Assuming deaths by natural mortality to be about $18 \%$, (an instantaneous natural mortality rate of 0.20 ), an annual discard plus tagging mortality rate of about $35 \%$ can be derived from the NYDEC results.

In the 1997 SAW25 (NEFSC 1997) and earlier assessments of summer flounder, a 25\% discard mortality rate was assumed for summer flounder released alive by anglers. However, two subsequent investigations of summer flounder recreational fishery discard, or hooking, mortality suggested that a lower rate was more appropriate. Lucy and Holton (1998) used field trials and tank experiments to investigate the discard mortality rate for summer flounder in Virginia, and found rates ranging from $6 \%$ (field trials) to $11 \%$ (tank experiments). Malchoff and Lucy (1998) used field cages to hold fish angled in New York and Virginia during 1997 and 1998, and found a mean short term mortality rate of $14 \%$ across all trials. Given the results of these studies conducted specifically for summer flounder, a $10 \%$ discard mortality rate was adopted in the Terceiro (1999) stock assessment and has been retained in all subsequent assessments.

Ten percent of the total B2 catch at age is therefore the basis of estimates of summer flounder recreational fishery discard mortality in aggregate numbers and weight (Table A16). The average annual CV of the recreational discards is $8 \%$ during 1982-2017. Recreational discard sampling intensity, estimates of dead discards at age, and dead discard mean weights at age are presented in Tables A17-A19.

## Calibrated ('New’) Marine Recreational Information Program (MRIP) Catch

In July 2018, the NOAA NMFS Marine Recreational Information Program (MRIP) released revised catch and effort estimates ('New’ MRIP; 1981-2017) as part of its recent transition from the Coastal Household Telephone Survey (CHTS) to the new, mail-based Fishing

Effort Survey (FES). Implemented in 2018, the FES is intended to be a more accurate method of collecting saltwater recreational fishing effort data from shore and private boat anglers on the Atlantic and Gulf coasts. As a result of the improved survey, FES estimates are a few to several times higher than telephone survey estimates and vary by state, type of fishing mode (by boat, shore, or for-hire), and reporting period. However, analyses indicate that the increase in effort estimates is because the FES does a better job of estimating fishing activity, not a sudden rise in fishing.

Calibration is a critical part of the transition to the new survey design. MRIP and academic consultants created a calibration model to re-estimate the fishing effort statistics back to 1981 from the 'Old’ CHTS "currency" to the 'New' FES "currency." The model accounts for the change in survey methods and the shift from landline telephone use to cell phone-only households. The model was peer reviewed and accepted by a panel of independent experts. MRIP completed a similar process to adjust historical catch rate estimates produced by the Access Point Angler Intercept Survey, the shoreside survey conducted by the states that collects information on angler catch from Maine to Mississippi. This adjustment accounted for any effects of the 2013 change to an improved sampling design for the intercept survey. The approach was peer reviewed and accepted by a panel of independent experts.

For comparison with the 'Old' estimates noted above, the 2018 MRIP calibrated estimate of summer flounder 2017 recreational landings is $4,565 \mathrm{mt}=10.064$ million lb , 3.2 times the old estimate. The 2018 MRIP calibrated estimate of 2017 recreational discards is $1,496 \mathrm{mt}=3.298$ million lb, 3.4 times the old estimate noted above. The time series of ‘New’ MRIP landings estimates in aggregate numbers and weight are presented in Table A20 and a comparison with the 'Old' MRFSS/MRIP estimates is made in Table A21 and Figure A2. The estimated recreational landings in numbers increased an average of $61 \%$, ranging from $+23 \%$ in 1983 to $+208 \%$ in 2017. The estimated recreational landings in weight increased an average of $73 \%$, ranging from $+30 \%$ in 1982 to $+215 \%$ in 2017. The largest absolute and percentage increases over time occurred for the NJ and NY Private/Rental boat fisheries. As a result of the increased landings, the sampling intensity of the recreational landings decreased to a level that would be considered marginally sufficient, generally between 200 and 300 mt per 100 lengths since 1999 (Table A22). Estimates of the landings and mean weights at age for the 'New’ MRIP estimates are presented in Tables A23-A24.

The 'New' MRIP discards estimates in aggregate numbers and weight are presented in Table A25 and a comparison with the 'Old' MRFSS/MRIP estimates is made in Table A26 and Figure A3. The estimated recreational discards in numbers changed by an average of $+81 \%$, ranging from $-16 \%$ in 1982 to $+235 \%$ in 2017. The estimated recreational discards in weight changed by an average of $+74 \%$, ranging from $-41 \%$ in 1994 to $+239 \%$ in 2017.

In the recompilation of the discards at age using the 'New' MRIP estimates, the available MRFSS and some newly available (since the previous 2013 SAW 57 benchmark assessment) ALS and VAS data was judged sufficient in quantity and coverage (in time, space, and fish length range) to allow direct characterization the length frequencies of the discards from sample data from 1993-2000. As a result of the increased discards, the sampling intensity of the recreational discards decreased but remained at a level that would be considered excellent, generally between 20 and 30 mt per 100 lengths since 1993 (Table A27). Estimates of the discards and mean weights at age for the 'New' MRIP estimates are presented in Tables A28A29.

## TOTAL FISHERY CATCH COMPOSITION

NER commercial fishery landings and discards at age, North Carolina winter trawl fishery landings and discards at age, and 'Old' MRFSS/MRIP recreational fishery landings and discards at age totals were summed to provide a total fishery catch at age for 1982-2017 (Table A30). Overall mean weight at age in the total catch was calculated as the weighted mean (by number in the catch at age) of the respective mean value at age from each fishery component (Table A31). Comparable information for the total catch with the 'new' MRIP estimates are provided in Tables A32-A33 and Figures A4-A5. The 2018 SAW-66 stock assessment model includes the 'New’ MRIP calibrated estimates of recreational landings and discards (Figure A6).

Using the 'Old’ MRIP estimates of recreational catch, commercial landings have accounted for $59 \%$ of the total landings and $49 \%$ of the total catch since 1993, when the current landings allocation system was implemented. Recreational landings accounted for $41 \%$ of the total landings and $34 \%$ of the total catch. Commercial discard losses accounted for about $10 \%$ of the total catch, and recreational discard losses about 7\%. Table A34 provides a tabulation of total catch in weight using the 'Old' MRFSS/MRIP estimates of the recreational fishery catch.

Using the 'New' MRIP estimates of recreational catch, commercial landings have accounted for $43 \%$ of the total landings and $36 \%$ of the total catch since 1993, when the current landings allocation system was implemented. Recreational landings accounted for $57 \%$ of the total landings and $47 \%$ of the total catch. Commercial discard losses accounted for about $7 \%$ of the total catch, and recreational discard losses about 10\%. Table A35 provides a tabulation of total catch in weight using the 'New' MRFSS/MRIP estimates of the recreational fishery catch.

A comparison of total fishery catches in numbers and weight with the 'Old' and 'New recreational catches is made in Table A36. The 'New' recreational catch estimates increased the 1982-2017 total catch in numbers by an average of $24 \%$ ( 4.6 million fish), ranging from $+9 \%$ in 1989 to $+73 \%$ in 2017. The 'New' recreational catch estimates increased the 1982-2017 total catch in weight by an average of $29 \%(3,908 \mathrm{mt}=8.616$ million lb ), ranging from $+12 \%$ in 1989 to +77\% in 2017.

## SPATIAL AND TEMPORAL DISTRIBUTION OF LANDINGS AND DISCARDS

Catch data from both recreational and commercial fisheries Vessel Trip Reports (VTRs) as well as observer reports were summarized to determine spatial trends within the fishery in recent decades. Resulting trends were used to assess the future need for research to understand any major changes in the spatial distribution of the stock. Both commercial (limited to fish trawlers and scallop dredges) and recreational gear catches were summarized in $\sim 5$ year intervals from the VTRs for 1994-2017. These data include both landed and discarded catch weights for commercial trips and catch numbers for recreational trips. Additional detail on commercial catch recorded by fisheries observers was also summarized for comparison. Although misreporting of the catch in VTR reports is considered low, the 'rough' accuracy of reported catch location is evident when comparing the spatial range being reported in observer records. Significant uncertainty in the validity of some VTRs exists, particularly for catches reported in areas well off the shelf and in inshore areas of SNE. Determining precise terms for removing VTR data due to misreporting of catch location is difficult, therefore all data is presented with reference to the aforementioned caveat regarding the validity of reported catch location (Miller and Terceiro 2018a MS).

## Commercial Fishery

The available VTR time series begins in 1994, just when summer flounder populations began rebuilding. Heaviest commercial catches (and by inference, effort) are reported just off of Cape Hatteras, concentrated around the entrances to Hudson Bay and Narragansett Bay, and offshore along the shelf edge from the Chesapeake Bay entrance through SNE (Figure A7; brown to purple squares). Large catches of summer flounder continued along the shelf from 2001-2005 with concentrations slightly farther north off DelMarVa (Figure A8). This northerly trend of offshore commercial catches continued through the present decade with the largest shelf catches now in SNE just south of Rhode Island. While a few inshore hot spots still remain (mainly at the entrance to Delaware and Chesapeake Bays and down the coast to Cape Hatteras), VTR reported commercial catches of summer flounder at its southern extent are reduced after 2005 (Figures A9A11).

Observer trip reports confirm similar spatial trends within the commercial fishery, though offshore outliers are mostly removed due to more accurate locations reported by observers. Recorded catch weights are reduced due to limited observer coverage, particularly in earlier years when the focus of the observer program was directed mainly towards documentation of protected species (Figures A12-A13). Catch densities from observer trips begin resembling a sub-sample of the commercial VTR catch data after 2000 (Figures A14-A17).

## Recreational Fishery

It is important to note that this recreational catch data is based only on party and charter boat trip reports and does not include recreational fishing by individual private boats or anglers or catch from shore. Recreational fishing catch (and by inference, effort) distribution from party and charter boats is relatively unchanged throughout the duration of the VTR database (Figures A18A22). One exception is a reduced catch south of the Chesapeake Bay after 2005. The highest density of recreational catch occurs in inshore waters from Delaware Bay along the coast to Narragansett Bay. Dominated by summer tourism, the high density of recreational catch follows the migratory pattern of larger fluke returning to inshore waters. Consistent with survey trends, the majority of large adult summer flounder are seen in highest densities along the New Jersey coastline, across the south coast of Long Island, Rhode Island and extending to the south coast of Massachusetts.

TOR A2. Present the survey data available, and describe the basis for inclusion or exclusion of those data in the assessment (e.g., indices of relative or absolute abundance, recruitment, state surveys, age-length data, etc.). Investigate the utility of commercial or recreational LPUE as a measure of relative abundance. Characterize the uncertainty and any bias in these sources of data.

## RESEARCH SURVEY INDICES OF ABUNDANCE

## NEFSC

The NEFSC stratified random bottom trawl surveys were first implemented in the fall of 1963 to sample the Gulf of Maine (GOM) waters off Maine and Nova Scotia southward to Hudson Canyon off New Jersey (NEFSC offshore strata 1-40 [depths equal to or greater than 27 meters = 15 fathoms]). Since 1968, the spring and fall trawl surveys have sampled the waters that encompass the summer flounder stock from the southern Gulf of Maine (GOM) off Massachusetts to Cape Hatteras, North Carolina, with the addition of offshore strata 61-76 (Clark 1979). Consistently sampled inshore strata 1-90 (depths generally $\leq 27$ meters [ 15 fathoms], except in the GOM) were added to the trawl survey sampling in the fall of 1975 . Both the spring and fall surveys were conducted using a Yankee 36 haddock net with roller sweep aboard the Fisheries Survey Vessel (FSV) Albatross IV and FSV Delaware II from 1963-2008, and then using a 4-seam, 3-bridle net using a rock-hopper sweep aboard the FSV Henry B. Bigelow since 2009. The NEFSC winter (flatfish) survey began in 1992 and ended in 2007, generally sampling offshore strata 1-17 and 61-75 using a flatfish net with a cookie sweep.

In the 2013 SAW 57 assessment (NEFSC 2013), the SFWG undertook a re-consideration of the strata included in indices for all three seasonal surveys, including those in the Great South Channel and Georges Bank. After examination of alternative strata set times series trends and precision, the SFWG decided to retain the winter, spring, and fall survey strata sets used in the assessments since 2002. Those standard strata sets have been retained in the current assessment.

The NEFSC spring and fall survey indices suggest that total stock biomass peaked during 1976-1977 and again during 2003-2007 (Table A37, Figure A23). The FSV Albatross IV (ALB) was replaced in spring 2009 by the FSV Henry B. Bigelow (BIG) as the main platform for NEFSC research surveys, including the spring and fall bottom trawl surveys. The size, towing power, and fishing gear characteristics of the BIG are significantly different from the ALB, resulting in different fishing power and therefore different survey catchability. Calibration experiments to estimate these differences were conducted during 2008 (Brown 2009), and the results of those experiments were peer reviewed by a Panel of three non-NMFS scientists during the summer of 2009 (Anonymous 2009, Miller et al. 2010). The Terms of Reference for the Panel were to review and evaluate the suite of statistical methods used to derive calibration factors by species before they were applied in a stock assessment context. Following the advice of the August 2009 Peer Review (Anonymous 2009), the methods proposed in Miller et al. (2010), and the precedents set in peer-reviews of stock assessments for haddock (Van Eeckhaute and Brooks 2010), yellowtail flounder (Legault et al. 2010), silver and red hake (NEFSC 2011a), and winter flounder (NEFSC 2011b), length-based calibration factors have been used to convert 2009-2017 spring and fall BIG survey catch number and weight indices to ALB equivalents.

The aggregate, spring calibration factors from Miller et al. (2010) are 3.2255 for numbers
(i.e., the BIG caught $\sim 3$ times more summer flounder numbers in aggregate than the ALB in the calibration experiment), and 3.0657 for weight. The aggregate, fall calibration factors are 2.4054 for numbers and 2.1409 for weight (Miller et al. 2010; Table A38). The effective total catch number length-based calibration factors vary by year and season, depending on the characteristics of the BIG length frequency distributions. The effective length-based calibration factors for numbers have ranged from 1.825 to 1.994 in the spring (average $=1.887$ ) and from 1.814 to 2.123 in the fall (average = 1.876; Tables A39-A41).

Age composition data from the calibrated NEFSC spring surveys indicate a substantial reduction in the number of ages in the stock between 1976-1990 (Table A42, Figure A24). For the period 1976-1981, fish of ages 5-8 were captured regularly in the survey, with the oldest individuals aged at 10-12 years. From 1982-1986, fish aged 5 years and older were only occasionally observed in the survey, and by 1986, the oldest fish observed in the survey were age 5. In 1990 and 1991, only three age groups were observed in the survey catch, and there was an indication that the 1988 year class was very weak. Since 1996, the NEFSC spring survey age composition has expanded significantly, with generally increasing abundance of age-3 and older fish up to age 16 for males and age 14 for females. Mean lengths at age from the NEFSC spring survey are presented in Table A43.

Summer flounder are frequently caught in the NEFSC fall survey at stations in inshore strata ( $<27$ meters $=15$ fathoms $=90$ feet) and at offshore stations in the 27-55 meter depth zone (15-30 fathoms, 90-180 feet) at about the same bathymetry as in the spring survey. NEFSC fall indices at-age are presented in Table A44. The NEFSC fall survey catches age-0 summer flounder in abundance, providing an index of summer flounder recruitment (Table A44, Figures A25-A26). NEFSC fall survey indices suggest an increase in abundance of age-2 and older fish since 1996. Mean lengths at age from the NEFSC fall survey are presented in Table A45. The standard strata set for summer flounder was not sampled in fall 2017.

A series of NEFSC winter trawl surveys was initiated in February 1992 to provide improved abundance indices for flatfish, including summer flounder. The surveys targeted flatfish concentrated offshore during the winter. A modified trawl was used that differed from the standard trawl employed during the NEFSC spring and fall surveys in that long trawl sweeps (wires) were added before the trawl doors to better herd fish to the mouth of the net, and the large rollers used on the standard gear were replaced on the footrope with a chain "tickler" and small spacing "cookies." The design and conduct of the winter survey (timing, strata sampled, and the use of the modified trawl gear) resulted in greater catchability of summer flounder compared to the other surveys. Most fish were captured in offshore strata 61-75 (27-110 meters; 15-60 fathoms) off the Delmarva and North Carolina coasts. Other concentrations of fish were found in strata 1-11, south of the New York and Rhode Island coasts, in slightly deeper waters. Significant numbers of large summer flounder were often taken along the southern flank of Georges Bank (strata 13-17). Similar to the other NEFSC surveys, there is strong evidence since the mid-1990s of increased abundance of age-3 and older fish relative to earlier years in the time series (Tables A47-A48). The NEFSC winter survey series ended in 2007.

## NEFSC FSV Henry B. Bigelow (BIG) indices as separate time series

In developing assessment model configurations for this assessment, the 2018 SFWG explored using the BIG indices as separate time series (2009-2016/2017), both to more easily incorporate recent research results on the efficiency of the BIG survey gear and to reduce
uncertainty due to the BIG-to-ALB calibration. 'Standard’ stratified mean numbers and weight per tow indices compile using BIG standard TOGA acceptance criteria are presented in Table A49.

Data from the 2015-2017 'twin trawl sweep study' experimental work was used to estimate mean trawl efficiency at length factors ('sweep q') to compute 'absolute’ indices per tow (i.e., what the survey catch per tow would be if trawl efficiency were 100\%) for the BIG 2009-2016/2017 survey catch. Application of the experimental efficiencies increases the computed catch per tow of the indices and, for the fall numeric indices, changes the rank order of the annual indices (i.e., 2016 is the highest in the 2019-2017 series; Figures A27-A28). These ‘absolute’ stratified mean numbers and weight per tow indices compiled using BIG standard TOGA acceptance criteria and efficiency estimates at length are presented in Table A50.

For use in population models, the BIG indices at age were also expressed as Swept Area Numbers (SWAN) indices, wherein the 'Absolute' indices are expanded to the total 'swept area' of the survey (expansion by average wing spread dimension, average tow speed, and annual survey area) to provide absolute estimates of population size (000s of fish at age). 'Standard,' 'Absolute,' and 'SWAN' indices for the NEFSC BIG spring and fall surveys are presented in Tables A51-A52.

## Massachusetts DMF

Spring and fall bottom trawl surveys conducted by the Massachusetts Division of Marine Fisheries (MADMF) show a decline in abundance in numbers of summer flounder from high levels in 1986 to record lows in the early 1990s. Both the MADMF spring and fall indices then increased to record high levels in the mid-2000s, and have been relatively stable since then (Tables A53-A54, Figure A29). The MADMF also captures a small number of age-0 summer flounder in a seine survey of estuaries, and these data constitute an index of recruitment (Table A55, Figure A30).

## Rhode Island DFW

Standardized spring and fall bottom trawl surveys have been conducted by the Rhode Island Department of Fish and Wildlife (RIDFW) since 1979 in Narragansett Bay and the state waters of Rhode Island Sound. Indices of abundance at age for summer flounder have been developed from the fall survey data using NEFSC fall survey age-length keys. The fall survey reached a time series high in 2009 and near high in 2011 (Table A56, Figure A31). An abundance index has also been developed from a set of fixed stations sampled monthly since 1990, which also reached a time series high in 2009 (Table A57, Figure A31). Recruitment indices are available from both the fall (Figure A30) and monthly fixed station surveys.

## University of Rhode Island Graduate School of Oceanography (URIGSO)

University of Rhode Island Graduate School of Oceanography (URIGSO) has conducted a standardized, year-round, weekly two-station trawl survey at Fox Island in Narragansett Bay and at Whale Rock in Rhode Island Sound since the 1950s, with consistent sampling since 1963. Irregular length-frequency samples for summer flounder indicate that most of the survey catch is of fish from ages 0 to 3. The average aggregate numbers-based index decreased from the 1959
until 1972, increased to a peak in the mid-1970s, decreased to a second low in 1990, and then increased to a time series peak in 2011 (Table A58, Figure A31).

## Connecticut DEEP

Spring and fall bottom trawl surveys are conducted by the Connecticut Department of Energy and Environmental Protection (CTDEEP). The CTDEEP surveys show a decline in abundance in numbers of summer flounder from 1986 to record lows in 1989. The CTDEEP surveys indicate recovery since 1989, and evidence of increased abundance at ages 2 and older since 1995. The 2011 spring and 2002 fall indices were the highest in the respective time series. Due to vessel engine failure, no complete fall survey was conducted in 2010 (Tables A59-A60, Figure A32). An index of recruitment is available from the fall series (Figure A33).

## New York DEC

The New York Department of Environmental Conservation (NYDEC) has conducted a small-mesh otter trawl survey in the Peconic Bay estuary at the eastern end of Long Island, New York since the mid-1980s; valid data for summer flounder are available since 1987. The NYDEC survey mean number per tow indices and length frequency distributions were converted to age using the corresponding annual NEFSC fall survey age-length keys (Table A61 Figure A32). An index of recruitment is available (Figure A33).

## New Jersey DFW

The New Jersey Division of Fish and Wildlife (NJDFW) has conducted a standardized bottom trawl survey since 1988, and indices of abundance for summer flounder are compiled from data collected from April through October (Table A62, Figure A34). The NJDFW survey mean number per tow indices and length frequency distributions were converted to age using the corresponding annual NEFSC fall survey age-length keys. The NJDFW index peaked in 2002 and has decreased since then. Over the last decade, most year classes are at or below average; however, the index of the 2005 year class was above average (Figure A33).

## Delaware DFW

The Delaware Division of Fish and Wildlife (DEDFW) has conducted a standardized bottom trawl survey with a 16 foot head-rope trawl since 1980 and with a 30 foot head-rope trawl since 1991, although due to a previously undocumented un-calibrated vessel change it was determined in this assessment that only the indices from 2003 and later are directly comparable. Recruitment indices (age 0 fish; one index from the Delaware estuary proper for 1980 and later, one from the inland bays for 1986 and later) have been compiled from the 16 foot trawl survey data (Tables A63-A64, Figure A35). Indices for age-0 to age-4 and older summer flounder have been compiled from the 30 foot head-rope survey (Table A65, Figure A34). The indices use data collected from June through October (mean number per tow) with age 0 summer flounder separated from older fish by visual inspection of the length frequency.

## Maryland DNR

The Maryland Department of Natural Resources (MDDNR) has conducted a standardized trawl survey in the seaside bays and estuaries around Ocean City, MD since 1972. Samples collected during May to October with a 16 foot bottom trawl have been used to develop a recruitment index for summer flounder (Table A66, Figure A36). This index suggests that weakest year classes in the time series recruited to the stock in 1988, 2005, and 2015, and the strongest in 1972, 1983, 1986, 1994, and 2009.

## Virginia Institute of Marine Science

The Virginia Institute of Marine Science (VIMS) has conducted a juvenile fish survey using trawl gear in Virginia rivers since 1955. An index of recruitment developed from the VIMS survey suggests weak year classes ( $<0.2$ fish per trawl) recruited to the stock in 1955, 1959, 1961-1962, 1966, 1968, 1970, and 1975, with strong year classes ( $>2.0$ fish per trawl) recruiting in 1956-57, 1963, 1971, 1979-1983, 1990-1991, and 1994. Recruitment indices since 1994 have been below average (Table A67, Figure A36).

The VIMS Chesapeake Bay Multispecies Monitoring and Assessment Program (ChesMMAP) was started in 2002, providing research survey samples from Chesapeake Bay. The ChesMMAP samples are dominated by age 0-2 summer flounder (Table A68, Figures A37A38).

The VIMS Northeast Area Monitoring and Assessment Program (NEAMAP) was started in Fall 2007, providing research survey samples along the Atlantic Coastal waters from Rhode Island to North Carolina, in depths of 20-90 feet (9-43 meters; Tables A69-A70, Figures A37A38).

## North Carolina DMF

The North Carolina Division of Marine Fisheries (NCDMF) has conducted a stratified random trawl survey using two 30 foot head-rope nets with 3/4" mesh cod-end in Pamlico Sound since 1987. An index of recruitment developed from these data suggests the weakest year class recruited to the stock in 1988, with the strongest year classes in 1987, 1996, 2001, and 2002 (Table A71, Figure A36). The survey normally takes place in mid-June, but in 1999 was delayed until mid-July. The 1999 index is therefore inconsistent with the other indices in the time series, and so the 1999 value has been excluded.

## NEFSC MARMAP and ECOMON

Ichthyoplankton data for summer flounder was collected during the MARMAP (19771987) and ECOMON (1999-2015) programs. Both MARMAP and ECOMON were designed as multi-species surveys, and sampling effort covered the entire northeast U.S. shelf from Cape Hatteras, North Carolina, to Cape Sable, Nova Scotia four to six times per year. MARMAP used primarily a fixed station design covering the sample area of each survey approximately evenly. ECOMON samples the same spatial extent of the shelf as MARMAP, but uses a randomstratified design based on the NEFSC bottom trawl survey design to collect samples from 47 strata. The area encompassed by each stratum determined the number of samples in each
stratum. The number of stations sampled during an ECOMON survey is approximately $30 \%$ less than that of MARMAP. The time series of larval indices from the MARMAP and ECOMON programs are used as indices of summer flounder spawning stock biomass (Table A72, Figure A39).

## FISHERY DEPENDENT INDICES OF ABUNDANCE

Fishery dependent catch rate data were modeled using generalized linear models in SAS software version 9 (SAS 2011) to developed standardized indices of abundance for summer flounder. The response variables were the continuous variable total landings or catch per day fished (for commercial trips) or per angler trip (for recreational trips), while the classification factors considered were the discrete variables year (the 'year' effect that in a main classification factors only model serves as the index of abundance), and various temporal, spatial, vessel, and regulatory classification characteristics.

The SAS GENMOD procedure fits generalized linear models that allow the mean of a population to depend on a linear predictor through a nonlinear link function and allow the response probability distribution to be specified from a number of probability (error) distributions. These include the normal, lognormal, binomial, Poisson, gamma, negative binomial (negbin), and multinomial (McCullagh and Nelder 1989). SAS GENMOD was used to model the fishery dependent catch rate data using lognormal (for ln-transformed rates), gamma, Poisson, and negative binomial (for untransformed rates) probability distributions, fitting a generalized linear model to the data by maximum likelihood estimation. There is no closed form solution for the maximum likelihood estimates of the parameters, so the procedure estimates the parameters of the model numerically through an iterative fitting process, with the covariances, standard errors, and p-values computed for the estimated parameters based on the asymptotic normality of maximum likelihood estimators (SAS 2011).

The estimates of- and changes in several goodness of fit statistics were used to evaluate the goodness of fit of the model and the significance of the classification factors: a) the ratio of the deviance (twice the difference between the maximum attainable log likelihood and the log likelihood of the model) to the degrees of freedom (DF); this statistic is a measure of "dispersion" and of fit of the expected probability distribution to the data (closer to 1 is better) and is comparable across models, b) the value of the log-likelihood (a measure of model fit), c) the computed AIC (a measure of model fit and performance, valid for a sequence of models within each distribution, and across models with the same type of data), d) whether or not the model converged (whether the negative of the Hessian matrix was positive definite, allowing valid estimation of the parameters and their precision), and e) the significance of the classification factors as indicated by the log-likelihood ratio statistics at the 5\% level (SAS 2011, Terceiro 2003b, Dick 2004, Maunder and Punt 2004).

A sequence of models, including from one factor to many factors, were fit and the differences/changes in the goodness of fit diagnostics used to determine the best model under each probability distribution assumption. A Type III analysis was used since it does not depend on the order in which the classification factors are specified. For the discrete variable Poisson and negative binomial error distributions, individual trip catch rate values were rounded to integer values.

## Commercial Dealer Landings Reports

Dealer report trawl gear landings rate (LPUE) data for summer flounder were modeled to compile standardized indices of abundance for summer flounder. Descriptive statistics indicated that the Dealer report Trawl gear landings rate distribution is over-dispersed in relation to a normal distribution, as the mean is larger than the mode, the variance is several orders of magnitude larger than the mean, and skewness is larger than zero. Simple visual inspection indicates the untransformed, interval-binned distribution is likely not normal, but rather a gamma, Poisson or negative binomial. However, the distribution of the ln-transformed landings rates suggests that a lognormal assumption could be appropriate for these data.

The distributions of the observed total landings were examined for three candidate classification variables - calendar quarter (QTR; 1 = Jan-Mar, 2 = Apr-Jun, etc.), 3-digit statistical area (AREA), and vessel tonnage class (TC; binned for vessels $<5$ gross registered tons [TC = 1], 5-50 [TC = 2], 51-150 [TC = 3], 151-500 [TC = 4], 501-1000 [TC = 5], and 1001 and larger $[T C=6]$ ), expressed as the cumulative sum of the total landings for each class level. The distribution by QTR indicated that about $40 \%$ of the landings were taken in the first calendar quarter. The distribution by statistical area indicated that about one-half of the total landings were taken in 5 areas: area 537 off RI and MA, area 616 off northern NJ and western Long Island, NY in the Hudson Canyon area; areas 621 and 622 off southern New Jersey and Delaware Bay, and area 626 off Delmarva. The distribution by tonnage class (TC) indicated that about $70 \%$ of the landings were taken by tonnage class 3 vessels. Total reported landings (lb), trips, days fished, and nominal annual LPUE (landings lb per DF), and LPUE scaled to the time series mean are presented in Table A73.

Given that the examination of the total landings lb per day fished frequency distributions indicated that the assumption of a negbin probability (error) distribution was most appropriate for the untransformed landings rate data and that the Deviance/DF (dispersion) statistic for the negbin model was closest to 1.0, the negbin four-factor YEAR-QTR-AREA-TC model was used as the best model for the Dealer Report trawl gear landings rate data for summer flounder. The YEAR estimated parameters (re-transformed and bias-corrected to linear scale) serves as the "year effect" index of abundance, and are compared to the nominal index in the top of Figure A40, with all series scaled to their respective time series means to facilitate comparison. All model configurations have a strong smoothing effect on the nominal indices from 1964 until about 2000, and then generally indicate a steeper increase in stock biomass through 2010 than does the nominal index. The lognormal model smoothed the nominal series most strongly through about 2000, but indicated the greatest increase in biomass since 2000. All models and the nominal index indicate a comparable decrease since 2011. The gamma and negbin models provided nearly identical results, although the negbin diagnostics indicated a better fitting model. The best-fitting negbin indices and their $95 \%$ confidence intervals are therefore compared with the nominal index in the bottom of Figure A40, with the series scaled to their means to facilitate comparison. The negbin annual indices, the annual Coefficients of Variation (CVs), and the $95 \%$ confidence intervals are presented in Table A74.

The data and analyses described above include only the data available from the NEFSC Dealer Report landings database. In developing these models, it was recognized that the inclusion of external information on the pattern of commercial fishery management regulations, which are known to affect both the rate of catch and behavior of fishermen, could impact the results. To that end, information on each state's open season (expressed as open or closed for
each year-month) and commercial fishery trawl trip limits (expressed as the limit in lb for each year/month) was added to the LPUE data set. For years prior to 1993, seasons were coded as open and trip limits were set at $100,000 \mathrm{lb}$ (the highest observed). This information was modeled both as covariates and as explicit classification variables. Unfortunately, attempts to develop valid model incorporating this external information failed, likely due to the lack of contrast of the cell means across classification strata. Most models failed to converge, and those that did 'converge' (i.e., stopped iterating due to the minimum residual step being attained) failed to provide valid parameter estimates for many of the classification variables.

## Vessel Trip Report (VTR)

## Commercial Fish Trawl Gear

Vessel Trip Report (VTR) fish trawl gear catch rate (landings plus discards; CPUE) data for summer flounder were modeled to compile standardized indices of abundance for summer flounder. Descriptive statistics indicate that the VTR trawl gear catch rate distribution is overdispersed in relation to a normal distribution, as the mean is larger than the mode, the variance is several orders of magnitude larger than the mean, and skewness is larger than zero. Simple visual inspection indicates the untransformed, interval-binned distribution is likely not normal, but rather a gamma, Poisson or negative binomial. However, the distribution of the ln-transformed landings rates suggests that a lognormal assumption could be appropriate for these data.

The distributions of the observed total catch were examined for four candidate discrete classification variables - calendar quarter (QTR; 1 = Jan-Mar, 2 = Apr-Jun, etc.), 3-digit statistical area (AREA), vessel tonnage class (TC; binned for vessels $<5$ gross registered tons [TC = 1], 5-50 [TC = 2], 51-150 [TC = 3], 151-500 [TC = 4], 501-1000 [TC = 5], and 1001 and larger [TC = 6]), and net mesh size category (MSH; LG [large] => 5 inches; SM [small] < 5 inches), expressed as the cumulative sum of the total catch for each class level. The distribution by QTR indicated that about half of the catch is taken in the first calendar quarter. The distribution by statistical area indicated that about one-third of the total catch was taken in just 3 areas: area 616 off northern NJ and western Long Island, NY in the Hudson Canyon area; area 537 off RI and MA, and area 626 off Delmarva. The distribution by tonnage class (TC) indicated that about two-thirds of the catch was taken by tonnage class 3 vessels. The distribution by mesh size indicated that large mesh trips accounted for $90 \%$ of the reported landings and $70 \%$ of the reported discards; the nominal reported discard rate (discards to total catch lb) was $2 \%$ for large mesh trips and 5\% for small mesh trips. Total catch, trips, days fished, nominal annual total catch lb per day fished (CPUE), and CPUE scaled to the time series mean is presented in Table A75.

Given that the examination of the total catch lb per day fished (CPUE) frequency distributions indicated that the assumption of a negbin probability (error) distribution was most appropriate for the untransformed catch rate data and that the deviance/DF (dispersion) statistic for the negbin model was closest to 1.0, the negbin five-factor YEAR-QTR-AREA-TC-MSH model was used as the best model for the VTR trawl gear catch rate data for summer flounder. The YEAR estimated parameters (re-transformed and bias-corrected to linear scale) serves as the "year effect" index of abundance for all three distributions, and are compared to the nominal index in the top of Figure A41, with all series scaled to their respective means to facilitate comparison. All model configurations have a moderate smoothing effect on the nominal indices, and indicate a slower decline in stock biomass since 2011 than does the nominal index. The
negbin indices and their $95 \%$ confidence intervals are compared with the nominal index in the bottom of Figure A41, again with the series scaled to their means. The negbin annual indices, the annual Coefficients of Variation (CVs), and the $95 \%$ confidence intervals are presented in Table A76.

## Recreational Party/Charter Boat

Vessel Trip Report (VTR) Party and Charter (P/C) boat catch rate (landings plus discards in numbers per trip; CPUE) data for summer flounder were modeled to compile standardized indices of abundance for summer flounder. Descriptive statistics indicate that the VTR P/C boat catch distribution is over-dispersed in relation to a normal distribution, as the mean is larger than the mode, the variance is 5-6 times larger than the mean, and skewness is larger than zero. Simple visual inspection indicates the untransformed distributions are likely not normal, but rather a gamma, Poisson or negative binomial. However, the distributions of the ln-transformed individual trip catch rates suggest that a lognormal assumption could be appropriate for these data.

The distributions of the observed total catch were examined for three candidate discrete classification variables - calendar month (MON), 3-digit statistical area (AREA), and VTR trip category (BOAT; Charter or Party boat) - expressed as the cumulative sum of the total catch for each class level. The distribution by QTR indicated that little of the catch is taken in the first or last calendar quarters, and that about $83 \%$ is taken during June, July, and August. The distribution by AREA indicated that about $67 \%$ of the total catch was taken in area 612 off northern NJ and western Long Island, NY; other areas with significant catch were 539 off RI and MA, 611 off eastern Long Island, NY, 614 off southern NJ, and 621 off Delmarva. The distribution by BOAT class indicated that about $75 \%$ was taken aboard Party boats, with the share between Party and Charter varying over time. Total catch, trips, anglers, nominal annual catch per trip (CPUE), and CPUE scaled to the time series mean for the boat types combined ( $\mathrm{P} / \mathrm{C}$ Boat) is presented in Table A77.

Initial reviews of the work suggested that the inclusion of external information on the pattern of recreational fishery management regulations, which are known to affect both the rate of catch and behavior of fishermen, could impact the results. To that end, information on each state's minimum retention size (SIZE) and possession (BAG) limit for each year from 1994-2017 was added to the basic VTR CPUE data set. In addition, the classification variable AREA (3digit statistical area) was dropped in favor of the STATE variable in the negbin model, to better correspond to the pattern of the regulatory information. Most of the P/C Boat total catch is reported by boats from NY and NJ, and about 10\% of the observations did not include state information and were dropped. First through third level interaction terms with YEAR (e.g., year*state, year*state*size, year*state*size*bag) were also added to the model to determine if those terms were estimable and/or significant (which has consequences for the use of the YEAR main effect as the index of abundance). The addition of the SIZE and BAG information to the YEAR-MON-STATE-BOAT model results in an improved model fit. The addition of interaction terms resulted in a converged model with improved fit, but many of the interaction term coefficients were inestimable. Therefore, the six factor YEAR-MON-STATE-BOAT-SIZE-BAG model (ST-SZ-BG) emerged as the best fitting, usable model. The six-factor ST-SZBG negbin modeled series indicates no overall trend in stock abundance through 2011, with a strong decreasing trend in stock abundance thereafter. The six-factor ST-SZ-BG negbin indices
and their $95 \%$ confidence intervals are compared with the nominal index in the top of Figure A42, with the series scaled to their means to facilitate comparison. The six-factor SIZE-BAG negbin annual indices, the annual Coefficients of Variation (CVs), and the $95 \%$ confidence intervals are presented in Table A78 and the bottom of Figure A42.

## Commercial Fishery Observer (OB)

## Fish Trawl Gear

Northeast Fishery Observer Program (NEFOP) catch rate (landings plus discards in pounds per trip; CPUE) data for summer flounder taken in observed fish trawl gear trips were modeled to compile standardized indices of abundance for summer flounder. Descriptive statistics indicate that the observed trawl gear catch rate distribution is over-dispersed in relation to a normal distribution, as the mean is (relatively) much larger than the mode, the variance is much larger than the mean, skewness is much larger than zero, and there is a high proportion of low total catch per trip observations (trips with < 250 lb per trip compose 50\% of the observations).

The distributions of the observed total catch were examined for three candidate classification variables - calendar quarter (QTR), 3-digit statistical area (AREA), and vessel tonnage class (TC; binned for vessels < 5 gross registered tons [TC = 1], 5-50 [TC = 2], 51-150 [TC = 3], 151-500 [TC = 4], 501-1000 [TC = 5], and 1001 and larger [TC = 6]), expressed as the cumulative sum or proportion of the total catch for each class level. The distribution by QTR indicated that about half of the total catch was observed in the first quarter (Jan-Mar), while only $11 \%$ was observed in quarter 2 (Apr-May). The distribution by statistical area indicated that about $67 \%$ of the total catch was observed in areas $525,537,612,616,622$, and 626 , with no other areas accounting for more than $4 \%$. The distribution by vessel tonnage class indicated that about $67 \%$ was observed aboard tonnage class (TC) 3 vessels. Total observed trips, hauls, catch, days fished, nominal annual catch per day fished (CPUE), and CPUE scaled to the time series mean are presented in Table A79.

The AICs for the gamma and negbin models (directly comparable because they are based on untransformed catch rates) were very close (gamma slightly lower/better). However, given that the examination of the total catch frequency distributions indicated that the assumption of a negbin probability (error) distribution was most appropriate for the untransformed catch rate data, and the Deviance/DF (dispersion) statistic for the negbin model was closest to 1.0, the negbin four-factor YEAR-QTR-AREA-TC model is indicated as the best model for the observed trawl gear catch rate data for summer flounder. The YEAR estimated parameters (re-transformed and bias-corrected to linear scale) serves as the "year effect" index of abundance for all three distributions, and are compared to the nominal CPUE in the top of Figure A43, with all series scaled to their respective means to facilitate comparison.

All modeled series indicate a steeper increase in stock biomass until 2010 than does the nominal series, and a comparable decrease since then. The Poisson series is the most variable over time, while the lognormal, gamma, and negbin series are less variable and match fairly closely. The negbin indices and their 95\% confidence intervals are compared with the nominal index in bottom of Figure A43, with the series scaled to their means to facilitate comparison. The negbin annual indices, the annual Coefficients of Variation (CVs), and the 95\% confidence intervals are presented in Table A80.

## Scallop Dredge Gear

Northeast Fishery Observer Program (NEFOP) catch rate (landings plus discards in pounds per trip; CPUE) data for summer flounder taken in observed fish trawl gear trips were modeled to compile standardized indices of abundance for summer flounder. Descriptive statistics indicate that the observed scallop dredge gear catch distribution is over-dispersed in relation to a normal distribution, as the mean is (relatively) much larger than the mode, the variance is much larger than the mean, skewness is much larger than zero, and there is a relatively high proportion of low total catch per trip observations.

The distributions of the observed total catch were examined for three candidate classification variables - calendar quarter (QTR), 3-digit statistical area (AREA), and vessel tonnage class (TC; binned for vessels < 5 gross registered tons [TC = 1], 5-50 [TC = 2], 51-150 [TC = 3], 151-500 [TC = 4], 501-1000 [TC = 5], and 1001 and larger [TC = 6]), expressed as the cumulative sum of the total catch for each class level. The distribution by QTR indicated that most of the observed total catch was distributed about equally between quarters 1,2 , and 4 , with only about $10 \%$ observed in the third quarter. The distribution by statistical area indicated that about half of the total catch was observed in areas 616 and 622 . The distribution by vessel tonnage class indicated that about 75\% of the total catch was observed aboard tonnage class (TC) 4 vessels. Total trips, hauls, catch, days fished, nominal annual CPUE, and CPUE scaled to the time series mean are presented in Table A81.

Given that the examination of the total catch frequency distributions indicated that the assumption of a Poisson/negbin probability (error) distribution was most appropriate for the untransformed catch rate data and the Deviance/DF (dispersion) statistic for the negbin model was closest to 1.0, the negbin four-factor YEAR-QTR-AREA-TC model is suggested as the best model for the observed scallop dredge gear catch rate data for summer flounder. The YEAR estimated parameters (re-transformed and bias-corrected to linear scale) serves as the "year effect" index of abundance for all three distributions, and are compared to the nominal CPUE in the top of Figure A44, with all series scaled to their respective means to facilitate comparison. All modeled series provide a comparable degree of smoothing of the nominal CPUE index, only slightly diverging from the nominal trend. The negbin indices and their $95 \%$ confidence intervals are compared with the nominal index in the bottom of Figure A44, with the series scaled to their means to facilitate comparison. The negbin annual indices, the annual Coefficients of Variation (CVs), and the 95\% confidence intervals are presented in Table A82.

## MRFSS/MRIP recreational fishery survey

Recreational fishery Marine Recreational Fishery Statistics Survey (MRFSS) / Marine Recreational Information Program (MRIP) catch rate from the intercept (field creel survey) sample data were modeled to compile standardized indices of abundance for summer flounder. Descriptive statistics indicate that the MRFSS/MRIP intercept catch distribution is overdispersed in relation to a normal distribution, as the mean is larger than the mode, the variance is 7 times larger than the mean, and skewness is larger than zero. Simple visual inspection indicates the untransformed distributions are likely not normal, but rather a negative binomial. For these data, only negative binomial models were fit.

The distributions of the intercept total catch were examined for four candidate discrete
classification variables - wave (2-month sampling intervals, e.g., January-February, Mar-April, etc. WAVE), state of landing (ST), fishing area (state or EEZ waters; AREA), and fishing mode (shore-based, private/rental boat, party/charter boat; MODE) - expressed as the cumulative sum of the intercept total catch for each class level. The first wave of the year (January-February) is not sampled from North Carolina to the north. Total catch in numbers, trips, and nominal annual CPUE (total catch per trip) for the intercept catch types combined (total catch) are presented in Table A83.

Initial reviews of the work suggested that the inclusion of external information on the pattern of recreational fishery management regulations, which are known to affect both the rate of catch and behavior of fishermen, could impact the results. To that end, information on each state’s minimum retention size (SIZE) and possession (BAG) limit for each year from 1981-2017 was added to the CPUE data set. First through third level interaction terms with YEAR (e.g., year*state, year*state*size, year*state*size*bag) were also added to the model to determine if those terms were estimable and/or significant (which has consequences for the use of the YEAR main effect as the index of abundance).

The addition of the SIZE and BAG information to the YEAR-WAVE-STATE-BOAT model resulted in an improved model fit. The addition of interaction terms resulted in a converged model with improved fit, but many of the interaction term coefficients were not significant and/or inestimable. Therefore, the six factor YEAR-WAVE-STATE-BOAT-SIZEBAG model (ST-SZ-BG) emerged as the best fitting, usable model. The six-factor ST-SZ-BG negbin modeled series indicates a very comparable trend compared with the nominal series. The six-factor ST-SZ-BG negbin indices and their $95 \%$ confidence intervals are compared with the nominal index in Figure A45, with the series scaled to their means to facilitate comparison. The six-factor SIZE-BAG negbin annual indices, the annual Coefficients of Variation (CVs), and the 95\% confidence intervals are presented in Table A84.

## NEFSC Cooperative Research Commercial Study Fleet

The NEFSC Cooperative Research Program partners with commercial fishing vessels to collect fine-scale, tow-level, self-reported catch data throughout a variety of fisheries on the Northeast Shelf. These data were examined to develop a catch-per-unit (CPUE) index for summer flounder (Gervelis 2018 MS). The index was developed using both time and area information and the annual estimate was a stratified-weighted mean CPUE by commercial statistical areas. No statistical modeling was attempted.

Self-reported tow-level data from Cooperative Research partner vessels (Study Fleet) that captured summer flounder (kept and discards) were included in the summer flounder CPUE index. All tows that caught at least 1 pound of summer flounder were included. The CPUE by time was calculated as the total catch (kept plus discards) of summer flounder in pounds divided by the length of the tow in hours.

$$
\left(U t o w=\frac{\left(k e p t_{\text {tow }}+\text { discards }_{\text {tow }}\right)}{\text { time }_{\text {tow }}}\right) .
$$

In an attempt to quantify "directed" trips, the tow level data were aggregated to the trip level and varying levels of summer flounder catch as a percentage of the total catch were also examined ( $10 \%, 25 \%, 40 \%, 75 \%$ ). All tows, by all vessels within in a given commercial statistical area (st) in a given year ( yr ) were averaged to produce an annual statistical area CPUE.

$$
U_{s t, y r}=\frac{\sum_{t o w s} U_{t o w, s t, y r}}{t o w s_{s t, y r}}
$$

The annual CPUE was calculated as the mean statistical area CPUE weighted by the area of the statistical boxes.

$$
U_{y r}=\frac{\sum_{s t} U_{s t, y r} \text { area }_{s t}}{\sum_{s t} \operatorname{area}_{s t}}
$$

All Study Fleet participant trawl vessels that captured at least 1 pound of summer flounder over the time series were included. All statistical areas where at least 1 pound of summer flounder were caught were included and all months were included. Tows with missing values for kept or discard catch were excluded. All tows with latitude/longitude outside the Northeast Shelf or tows longer than 12 hours were also excluded.

An examination of the NEFSC Study Fleet summer flounder trawl vessel effort in time and space was found to be reasonably representative of the overall trawl fishery for summer flounder. The nominal (All trips) CPUE index showed an overall increasing trend with a peak in 2013. The amount of vessels and tows also increased during this time period until reaching its peak in 2014. While number of vessels and tows dropped slightly in 2015 and 2016 respectively, CPUE declined further to nearly half of its peak from 2013. CPUE then increased slightly in 2017. (Table A85 and Figure A46). The CPUE indices generated for the various quantification levels (All, $10 \%, 25 \%, 40 \%$ and $75 \%$ ) for 'directed' trips all showed similar trends to one another. Sample year 2013 showed more variability in annual CPUE across the different levels than the other years in the time period.

## 2018 SAW-66 SFWG Conclusion on Utility as Indices of Abundance

The SFWG evaluated the utility of the nominal and standardized fishery dependent landings- and catch-per unit effort based indices as measures of abundance for the summer flounder stock assessment. The SFWG concluded that the calculation of directed effort in the fishery dependent data is problematic. For the commercial data, the effort information is dependent on the accurate recording by the fishermen themselves. The collection of this data is not a focus of their operation, however, and therefore metrics like the fishing time or length of tow may not be accurate and could therefore provide a biased CPUE index. There is a lack of consistency in the reporting requirements for parts of the commercial VTR time series; the instructions for how effort is reported have changed.

For the recreational data, the calculation of directed effort is even more problematic. In this analysis, all trips which caught summer flounder were used. There are several different ways to define summer flounder trips. However, there is variation in the number of rods and reels (gear quantity) and the time of fishing for each trip that may not be completely or accurately reported. The catch is also inconsistently reported in the for-hire recreational VTRs, with it being provided incorrectly as pounds on these self-reported forms. In total, these elements make the calculation of effort challenging when working with commercial and recreational fishery data time series.

The SFWG noted that over the long term, and especially since fishery quotas were
instituted in the early 1990s, there have been a number of regulatory changes which vary in timing and magnitude for each state (primarily seasonal closures, seasonal trip/possession limits, and minimum size limits). This information is not part of the commercial and recreational catch databases and so must be developed independently and integrated within the generalized model used for index standardization. This information could not be modeled adequately as covariates or classification variables within the generalized model framework (i.e., inability to develop a model which converges and produces valid parameter estimates) for the commercial fishery data.

The commercial trawl standardized indices generally indicate trends in abundance comparable to the fishery independent survey indices (higher in the late 1970s, lower in the early 1990s, higher again during the 2000s). The recreational fishery standardized indices, for which inclusion of regulatory measures in the models were successful, indicated weaker trends in abundance than either the commercial indices or most fishery independent survey indices.

The top of Figure A47 compares the time series trends of the fishery dependent nominal indices of abundance and the NEFSC spring survey biomass index, scaled to the terminal year (2017) to facilitate comparison (the Study Fleet All trips index is plotted as a nominal index). The bottom of Figure A47 makes the same comparison including the fishery dependent model indices of abundance (the Study Fleet $40 \%$ trips index is plotted as a model index). The modeling difficulties call into question the utility of both the nominal and model-based fishery dependent standardized indices as unbiased measures of summer flounder abundance. The SFWG felt the standardization procedure was still subject to an unknown, likely negative, bias. In addition, the SFWG felt the multiple fishery-independent surveys available to this assessment had sufficient spatial coverage such that inclusion of the fishery-dependent indices was not necessary, as might be the case for an assessment that lacked adequate fishery independent sampling. Based on these concerns, the SFWG recommended that the fishery dependent standardized indices of abundance not be used in the summer flounder assessment model.

TOR A3. Describe life history characteristics and the stock's spatial distribution (for both juveniles and adults), including any changes over time. Describe factors related to productivity of the stock and any ecosystem factors influencing recruitment. If possible, integrate the results into the stock assessment.

## AGEING RESEARCH

Historical studies of summer flounder age and growth include those of Poole (1961), Eldridge (1962), Powell (1974), Smith and Daiber (1977), Henderson (1979), and Shepherd (1980). A summer flounder ageing workshop held in 1980 (Smith et al. 1981) noted that these early studies provided differing interpretations of the growth zones on summer flounder scales and otoliths. After comparative study by fisheries biologists from along the Atlantic coast, the workshop concluded that both structures followed the generalized temperate waters pattern of rapid growth during early summer through early winter. Scales were identified as the better structure for ageing, being preferred over otoliths due to the possibility of poor otolith calcification and/or resorption. Spawning was noted to occur to from early September in the north through the following March in the south. For uniformity, January 1 was considered the birthday, with fish not considered one year old until passing their first summer, to eliminate the possibility of fall spawn fish being classified as age 1 the following January. The 1980 workshop effectively set the first coast-wide conventions for ageing summer flounder, and importantly concluded that the minimum observed mean length of age 1 fish should be at about 17-18 cm and of age 2 fish at about 28-29 cm (Smith et al. 1981).

A second summer flounder ageing workshop was held in 1990 (Almeida et al. 1992) in response to continuing confusion among summer flounder biologists over the proper interpretation of the conventions established by the 1980 workshop (Smith et al. 1981). Several issues were addressed, including the differences in processing and interpreting scales and otoliths, the age classification of the first distinct annulus measured from the focus, and consideration of new studies completed since the 1980 workshop. The 1990 workshop agreed to accept the summer flounder ageing criteria provided in Dery (1988), and in particular noted that first annulus formation for a given cohort could occur after 18-21 months of growth for fish spawned in the north in the fall, and after 10-16 months of growth for fish spawned in the south early the following spring. The latter conclusion was based on a review of the work of Szedlmayer and Able (1992), which validated the first year growth assumption and interpretation of the first annulus. The 1990 workshop most importantly concluded that there was consistency in ageing techniques and interpretation and that first year growth for summer flounder was extremely rapid. The workshop noted the potential for fish born early in the calendar year and inhabiting estuarine areas of the mid-Atlantic to reach 30 cm by their first winter and be classified as age 0, in support of the Poole (1961) and Szedlmayer and Able (1992) conclusions (Almeida et al. 1992).

Work performed in preparation for the Stock Assessment Workshop (SAW) 22 stock assessment (NEFSC 1996b) indicated a major expansion in the size range of 1-year old summer flounder collected during the 1995 and 1996 Northeast Fisheries Science Center (NEFSC) winter bottom trawl surveys. The work also brought to light developing differences between ages determined by NEFSC and North Carolina Division of Marine Fisheries (NCDMF) fishery biology staffs. Age structure (scale) exchanges were performed prior to the SAW 22 assessment to explore these differences. The results of the first two exchanges were reported at SAW 22
(NEFSC 1996b) and indicated low levels of agreement between age readers at the NEFSC and NCDMF (31 and 46\%). During 1996, research was conducted to determine inter-annular distances and to back-calculate mean length at age from scale samples collected on all NEFSC bottom trawl surveys (winter, spring and fall) for comparison with NCDMF commercial winter trawl fishery samples. While mean length at age remained relatively constant from year to year, inter-annular distances increased sharply in the samples from the 1995-1996 winter surveys, and increased to a lesser degree in samples from other 1995-1996 surveys. As a result, further exchanges were suspended pending the resolution of an apparent NEFSC ageing problem.

Age samples from the winter 1997 bottom trawl survey, aged utilizing both scales and otoliths by only by one reader, subsequently indicated a similar pattern as the previous two winter surveys (i.e., several large age 1 individuals), and some disagreement between scale and otolith ages obtained from the same fish. Because of these problems, a team of five experienced NEFSC readers was formed to re-examine the scales aged from the winter survey. After examining several hundred scales, the team determined that re-ageing all samples from 19951997 would be appropriate, including all winter, spring, and fall samples from the NEFSC and Massachusetts Division of Marine Fisheries (MADMF) bottom trawl surveys and all samples from the commercial fishery. The age determination criteria remained the same as those developed at the 1990 workshop (Almeida et al. 1992) and described in the ageing manual utilized by NEFSC staff (Dery 1988, 1997). Only those fish for which a $100 \%$ agreement of all team members was attained were included in the revised database. The data from the re-aged database were used in analyses in the SAW 25 assessment (NEFSC 1997).

A third summer flounder ageing workshop was held at the NEFSC in 1999, to continue the exchange of age structures and review of ageing protocols for summer flounder (Bolz et al. 2000). Participants at this workshop concluded that the majority of ageing disagreements in recent NEFSC-NCDMF exchanges had arisen from inconsistency among readers in the interpretation of marginal scale increments due to highly variable timing of annulus formation and in the interpretation of first year growth patterns and classification of the first annulus. The workshop recommended regular samples exchanges between NEFSC and NCDMF, and further analyses of first year growth. Subsequently, Sipe and Chittenden (2001) concluded that sectioned otoliths were the best structure for ageing summer flounder over the age range from 0 to 10 years. Beginning in 2001, both scales and otoliths began to be routinely been collected in all NEFSC trawl surveys for fish larger than 60 cm .

An exchange of NEFSC and NCDMF ageing structures for summer flounder occurred again in 2006, after the SAW Southern Demersal Working Group (SDWG) listed the age sample exchange as a high research priority. This exchange examined samples from fish aged 1 to 9 (2376 cm total length) and determined that the consistency of ageing between NCDMF and the NEFSC was at an acceptable level. During 2006-2011, overall summer flounder ageing precision, based on sample-size weighted intra- and inter-reader ageing agreement, averaged $86 \%$ with an overall Coefficient of Variation (CV) of 3\%. The degree of precision is very similar for structures sampled from surveys and the commercial fisheries. Figures A48-A49 show the intra-ager age bias and percent agreement for the 2011 NEFSC trawl survey age samples, and Figures A50-A52 show the intra-ager age bias and percent agreement for the 2011 NEFSC commercial fishery age samples. These patterns are typical of those for NEFSC fishery and survey scale samples collected since 2000.

NEFSC commercial fishery and survey samples began to transition from scales only to scales and otoliths (to allow comparison and possible calibration) beginning in 2009. A fourth
summer flounder ageing workshop was held at VIMS in 2014, to continue the exchange of age structures and review of ageing protocols for summer flounder. A comparison of scale and otoliths ages from 619 samples collected from 2009 to 2013 indicated was good agreement for all age classes up to 12 years of age (Figure A53). However, there was a minor systematic bias detected with otoliths having slightly higher ages on average. Participants at the 2014 workshop concluded that sectioned otoliths were the desired hard-part to use (Eric Robillard, NEFSC, personal communication 2015).

In 2017, ASMFC sponsored another ageing workshop. For sectioned otoliths the agreement between ageing laboratories was found to be above $80 \%$ with low variation and no systematic bias (ASMFC 2017 MS). Both NEFSC survey and commercial samples were completely transitioned to otoliths beginning in 2015 with the 2015 spring trawl survey and quarter 1 commercial samples. Figures A54-A55 show the intra-ager age bias and percent agreement for the 2016 NEFSC trawl survey and commercial fishery quarter 1 age samples, which are typical of the otolith samples collected since 2009.

## GROWTH

## Trends in NEFSC survey mean length and weight at age

The NEFSC winter, spring, and fall trawl survey sample data were examined for trends in mean length and weight by sex and age. Age collections for the spring and fall series begin in 1976; the winter survey was conducted during 1992-2007. Data are generally presented for ages 0 through age 10; samples for ages 8 and older are sporadic and variable, although they are more numerous and consistent since 2001.

The winter and spring series indicate no strong trend in the mean lengths of ages 1-2 for sexes combined. For ages 3-6, there is an increasing trend in mean length from 1976 to about 1990, and a decreasing trend since then, and a slight decreasing trend in the winter survey for ages 7-8 (Figures A56-A57). In the fall series, there is no obvious trend for ages 0-1, but there are relatively strong decreasing trends in mean length for combined sexes for ages 2 and older since the mid-1990s (Figure A58).

Individual fish weight collection on NEFSC trawl surveys began in 1992. In general, the patterns in mean weight reflect those in mean length, with a decreasing trend in mean weight evident for ages 3 and older (Figure A59-A61). Trends in the mean weights at age in the total, combined sexes fishery catch (landings plus discards) exhibit a comparable pattern, with strongest declining trends since the 1990s for ages 3 and older (Figure A62).

Trends by sex and age for all three seasonal survey series follow comparable patterns. There are no trends in the mean lengths for ages $0-1$, with an overall declining trend since the 1990s for ages 2 and older. Mean lengths of ages 3 and older show decreasing trends for both sexes (Figures A63-A65).

## von Bertalanffy Parameters

Early estimates of summer flounder age and growth were limited in spatial and temporal scope, and include those of Poole (1961), Eldridge (1962), Smith and Daiber (1977) and Henderson (1979). Smith and Daiber (1977) used data from 319 fish sampled from Delaware Bay during 1966-1968 to estimate the von Bertalanffy asymptotic length parameter, Linf, for
males of 62 cm and for females of 88 cm , although their observed maximum ages were only age 7 for males and age 8 for females. Henderson (1979) estimated Linf for sexes combined to be 92 cm and the von Bertalanffy growth rate parameter, k , to be 0.21 , based on fish sampled from the commercial fishery in 1976 with a maximum age of 10.

Fogarty (1981) used data from the NEFSC spring and fall trawl surveys for 1,889 scale samples obtained during 1976-1979 to estimate von Bertalanffy growth parameters. Fogarty concluded that female summer flounder attained a significantly larger asymptotic size than males, but that there was not a significant difference in the growth rate coefficient k. Fogarty (1981) estimated that the parameters for males were $\operatorname{Linf}=72.7 \mathrm{~cm}, \mathrm{k}=0.18$, with maximum age of 7; the parameters for females were $\operatorname{Linf}=90.6 \mathrm{~cm}, \mathrm{k}=0.16$, with maximum age of 10 .

Pentilla et al. (1989) provided information on mean lengths at age for both sexes of summer flounder sampled during NEFSC trawl surveys during 1975-1988; the summer flounder ages have since been corrected to be one year younger (Almeida et al. 1992; JM Burnett III, NEFSC, personal communication 1997; Bolz et al. 2000). The data from Pentilla et al. (1989) provide parameters for males of $\operatorname{Linf}=72.7 \mathrm{~cm}, \mathrm{k}=0.18$, with maximum age of 11 ; parameters for females of $\operatorname{Linf}=90.7 \mathrm{~cm}, \mathrm{k}=0.16$, with maximum age of 11 ; and parameters for sexes combined of $\operatorname{Linf}=81.6, \mathrm{k}=0.17$, with maximum age of 11 .

In the current work, the NEFSC trawl survey data for 1976-2016 (ages for 2017 were not yet available) were used to estimate growth parameters for males, females, and sexes combined for the full time series and for seven multi-year (generally five year) bins. The full time series data provide parameters for males ( $\mathrm{n}=19,424$ ) of $\operatorname{Linf}=63.9 \mathrm{~cm}, \mathrm{k}=0.18$, with maximum length of 67 cm (age 6) and age of 15 (length $56-57 \mathrm{~cm}$ ); parameters for females ( $\mathrm{n}=20,689$ ) of Linf $=80.6 \mathrm{~cm}, \mathrm{k}=0.18$, with maximum length of 82 cm (age 11) and age of 14 (length 76 cm ); and parameters for sexes combined ( $n=40,942$, including small fish of undetermined sex) of Linf $=83.6, \mathrm{k}=0.14$, with maximum age of 15 (Table below, Figure A66).

| Study | N fish | Max age (M, F) | Linf (M, F, B) | k (M, F, B) |
| :--- | :---: | :---: | :---: | :---: |
| Smith \& Daiber (1977) | 319 | 7,8 | 62,88 | n/a |
| Henderson (1979) | n/a | 10 | 92 | 0.21 |
| Fogarty (1981) | 1,889 | 7,10 | $72.7,90.6$ | $0.18,0.16$ |
| Pentilla et al. (1989) | n/a | 11,11 | $72.7,90.7,81.6$ | $0.18,0.16,0.17$ |
| Current assessment | 40,942 | 15,14 | $63.9,80.6,83.6$ | $0.18,0.18,0.14$ |

The seven multi-year bins were for the years 1976-1981, 1982-1987, 1988-1993, 19941999, 2000-2005, 2006-2011, and 2012-2016. Von Bertalanffy parameters were estimated for males, females, and sexes combined. For the bins with more limited age ranges, the asymptote of the von Bertalanffy function is not well defined, and so the Linf estimates tend to be unrealistically high and the $k$ estimates tend to be low. In some cases the model did not converge to provide realistic model parameter estimates, although the predicted lengths over the observed age range were still realistic. The multi-year bin growth curves are tightly clustered through age 5 for females, with some divergence at older ages (in part due to the lack of older ages as noted above), with the most recent bin (2012-2016) indicating smaller predicted lengths at age than in previous years. The growth curves are more variable for males, and therefore for sexes combined, again with the most recent 2012-2016 curve indicating smaller predicted lengths for older males, and for all ages when sexes are combined (Figures A67-A68).

## Length-Weight parameters

The length-weight parameters used to convert commercial and recreational fishery landings and discards sampled lengths ( cm ) to weight ( kg ) are taken from the work of Lux and Porter (1966; L\&P), which used individual fish lengths and weights from 2,051 fish collected during 1956-1962 to compute the parameters by calendar quarters. Wigley et al. (2003; Wigley) updated the length-weight parameters used in audits of the NEFSC trawl survey data, using individual length and weight information from 9,373 fish for 1992-1999.

In the current work, individual length and weight information from 32,507 fish from the NEFSC trawls surveys for 1992-2017 were used to estimate length-weight parameters for comparison with the earlier studies to judge whether changing from the historical Lux and Porter (1966) parameters would be justified. Parameters were estimated for the entire 1992-2017 time series, for 5 multi-year blocks (1992-1995, 1996-2000, 2001-2005, 2006-2010, and 2011-2017), and by survey seasonal time series (winter 1992-2007, spring 1992-2017, and fall 1992-2016).

A comparison among these alternative compilations indicates very little difference in the estimated length-weight relationships from Lux and Porter (1966), Wigley et al. (2003), and the current examination for the NEFSC trawl survey data. The curves are virtually identical through a total length of 62 cm (the combined surveys mean length of age 7 fish; age 7 and older fish compose the assessment model 'plus group'), a threshold below which over $95 \%$ of the fishery catch has occurred (see the 'SVs Age 7 xl’ vertical line in Figures A69-A70). Above 62 cm, the quarterly length-weight curves of Lux and Porter (1996) bracket the Wigley et al. (2003) and survey multi-year bin curves in the expected way, with first quarter, pre-spawning fish larger in weight at length than fourth quarter, post-spawning fish (Figure A69). In a comparison with survey seasonal curves, the curves are again nearly identical through 62 cm . Above 62 cm , the quarterly length-weight curves of Lux and Porter (1996) align with the survey seasonal curves in the expected way, with the seasonal winter (post-spawning) and spring (pre-spawning) curves close to the Lux and Porter first quarter curve, with the fall survey (September; nearest to peak spawning) curve closest to the Lux and Porter third quarter curve (Figure A70). Based on the consistency of the L-W relationship over these comparisons, the Lux and Porter (1966) commercial fishery quarterly length-weight parameters were retained for this assessment.

## K Condition Factor

Fulton's condition factor, K, is a measure of the relationship between fish length and weight that attempts to quantify the 'condition' of an individual or group of fish. Nash et al. (2006) note that it was Heincke (1908) who first used K as a measure of 'condition,' building on the 'cubic law' of growth in weight first introduced by Fulton (1904; K = x*weight / length**3, where x is a constant to scale K near 1). Nash et al. (2006) further point out that it was Ricker (1954) who first attributed the factor K to Fulton and coined the name 'Fulton’s condition factor.'

The NEFSC winter, spring, and fall trawl survey sample data were examined for trends in condition factor by season and sex. Individual fish weight collection began on NEFSC surveys in spring 1992; the winter survey was conducted during 1992-2007. There are no long-term trends in condition factor by season or sex (Figures A71-A73).

## SEX RATIO

## Sex Ratio in NEFSC Survey Raw Sample Data

The NEFSC winter, spring, and fall trawl survey raw sample data (not the stratified indices by sex and age, although they generally show similar patterns) were examined for trends in sex ratio by season and age, expressed as the proportion of females at age. The spring and fall series have sufficient data for the compilation beginning in 1976; the winter survey was conducted from 1992-2007. In the winter survey, the proportion of females showed no trend for age 1 and the mean proportion was $49 \%$. For ages 2 and 3 , the proportion decreased from about $0.7-0.8$ in the early 1990s to $0.4-0.6$ in the mid-2000s. For ages 4 to 6 , the proportion decreased from about 0.8-1.0 in the early 1990s to about 0.7 in the mid-2000s. For ages 7 and older that compose the 'plus group,' the proportion ranged from 0.8 to 1.0 over the series (Figure A74).

In the spring survey, the proportion of females showed no trend for age 1 and the time series mean proportion was 0.4 ; the mean for 2012-2016 was 0.4 . For ages 2 and 3 , the proportion has decreased from about 0.6-1.0 in the early 1990s to about 0.5 since 2000; the means for 2012-2016 were about 0.4 . For ages 4 and 5 , the proportion has decreased from a range of 0.8 to 1.0 in the early 1990s to about 0.5 in the mid-2000s; the means for 2012-2016 were 0.4 and 0.5 . For ages $6-8$ the proportion ranged from 0.5 to 1.0 with no trend for most of the series, but has most recently decreased to near 0.5 ; the means for 2012-2016 were about 0.7 (Figure A75).

In the fall survey, the proportion of females shows no trend for age 0 and the mean proportion was $33 \%$. For ages 1 and 2, the proportion has decreased from about 0.5-0.6 in the 1980s to $0.4-0.5$ by the 2010s; the means for 2012-2016 were about 0.3 . The proportions at ages 3 and 4 have strongly decreased from about 0.9 through the late 1990s to about 0.5 by the 2010s; the means for 2012-2016 were 0.4 and 0.5 . For ages $5-8$ and older the proportions have most recently decreased to about 0.7 ; the means for 2012-2016 were $0.7,0.8,0.7$, and 0.9 (Figure A76).

## Sex Ratio in NEFSC stratified mean indices

NEFSC stratified mean abundance indices (numbers per tow) were calculated for the winter (1992-2007), spring and fall (1976-2016) series. The spring and fall BIG 2009-2016 indices were calibrated to ALB equivalents using calibration factors at length. The male and female indices generally follow similar trends over time (Figures A77-A78).

As in the raw sample data, the sex ratio in the NEFSC stratified indices has changed over the last decade, with generally decreasing proportions of females at ages 2 and older. In the winter indices, the proportion of females showed no trend for age 1 and the mean proportion was $46 \%$. For ages 2,3 , and 4 , the proportion has decreased from about $0.6-0.8$ in the early 1990 s to about 0.4-0.5 by 2007. For ages 5 and 6, the proportion has decreased from about 0.8-1.0 in the early 1990s to about 0.6-0.7 by 2007. For ages 7 and older that compose the 'plus group,' the proportion has ranged from 0.8 to 1.0 over the series (Figure A77).

In the spring indices, the proportion of females has an increasing trend for age 1 from about 0.3 to 0.5 , and the mean proportion was $40 \%$. For ages 2,3 , and 4 , the proportion has decreased from about 0.6-0.7 in the late 1970s to about 0.3-0.5 since 2000. For ages 5 and older, the indices during the 1980s-1990s are generally very small values (often $<0.001$ fish per tow, and so round to 0 and appear 'missing' in the figures) and the proportion of females over the
series is variable without a strong trend. Most recently the proportion of females at ages 5 and older has decreased to less than 0.6 (Figure A79).

In the fall survey, the proportion of females shows no trend for age 0 and the mean proportion was 0.3 . For ages $1-3$ the proportion has decreased from about $0.5-0.6$ in the 1980 s to $0.4-0.5$ by 2012-2016. The proportions at ages 4 to 7 have strongly decreased from about 0.8 through the late 1990s to about 0.3-0.8 by 2012-2016; proportions at age 8 are highly variable (Figure A80).

## MATURITY

Morse (1981) examined the reproductive characteristics of summer flounder using a special collection sampled during the 1974-1979 NEFSC trawl surveys ( 2,910 total fish). Morse (1981) estimated that the length at $50 \%$ maturity (L50\%) was 24.7 cm for males and 32.2 cm for females. O'Brien et al. (1993) used NEFSC fall trawl survey data for 1985-1989 (875 total fish) and estimated $\mathrm{L} 50 \%$ to be 24.9 cm for males and 28.0 cm for females.

The maturity schedule at age for summer flounder used in the 1990 SAW 11 and subsequent stock assessments through 1999 was developed using NEFSC fall survey maturity data for 1982-1989 (G. Shepherd, NEFSC, personal communication, July 1, 1990; NEFSC 1990; Terceiro 1999). The 1990 SAW 11 work indicated that the median length at maturity ( $50^{\text {th }}$ percentile, $\mathrm{L}_{50}$ ) was 25.7 cm for male summer flounder, 27.6 cm for female summer flounder, and 25.9 cm for the sexes combined. Under the ageing convention used in the 1990 SAW 11 and subsequent assessments (Smith et al. 1981, Almeida et al. 1992, Szedlmayer and Able 1992, Bolz et al. 2000), the median age of maturity ( $50^{\text {th }}$ percentile, $\mathrm{A}_{50}$ ) for summer flounder was determined to be age 0.1 years for males and 0.5 years females (i.e., fish about $13-17$ months old, based on the actual spawning month and the January 1 ageing convention relative to fall sampling). Combined estimated (logistic regression) maturities indicated that at peak spawning time in the autumn (November 1), $38 \%$ of age 0 fish were mature, $72 \%$ of age 1 fish were mature, $90 \%$ of age 2 fish were mature, $97 \%$ of age 3 fish were mature, $99 \%$ of age 4 fish were mature, and $100 \%$ of age 5 and older fish (age $5+$ ) were mature. The maturities for combined sexes age 3 and older (age 3+) were rounded to $100 \%$ in the 1990 SAW 11 and subsequent assessments through 1999.

The NEFSC maturity schedules are based on simple gross morphological examination of the gonads, and it was suggested in the early 1990s that they may not have accurately reflected (i.e., overestimated) the true spawning potential of the summer flounder stock, especially for age-0 and age- 1 fish. It was also noted, however, that spawning stock biomass (SSB) estimates based on age-2 and older fish showed the same long term trends in SSB as estimates which included age 0 and 1 fish in the spawning stock. A research recommendation that the true spawning contribution of young summer flounder to the SSB be investigated was included in research recommendations from summer flounder stock assessments beginning in 1993 (NEFSC 1993).

Research at the University of Rhode Island (URI) by Drs. Jennifer Specker and Rebecca Rand Merson (hereafter referred to collectively as the "URI 1999" study) attempted to address the issue of the true contribution of young summer flounder to the spawning stock. The URI 1999 study examined the histological and biochemical characteristics of female summer flounder oocytes to determine if age-0 and age- 1 female summer flounder produce viable eggs and to develop an improved guide for classifying the maturity of summer flounder collected in NEFSC
surveys (Specker et al. 1999, Merson et al. 2000, Merson et al. MS 2004). The URI 1999 study examined 333 female summer flounder ( 321 aged fish) sampled during the NEFSC winter 1997 survey (February 1997) and 227 female summer flounder ( 210 aged fish) sampled during the NEFSC fall 1997 survey (September 1997) using radio-immunoassays to quantify the biochemical cell components characteristic of mature fish. In light of the completion of URI 1999 study to address the long-standing research recommendation, the maturity data for summer flounder for 1982-1998 were examined in the 2000 SAW 31 assessment (NEFSC 2000) to determine if changes in the maturity schedule were warranted.

The NEFSC 1982-1998 and URI 1999 maturity determinations disagreed for $13 \%$ of the 531 aged fish, with most (10\%) of the disagreement due to NEFSC mature fish classified as immature by the URI 1999 histological and biochemical criteria. The URI 1999 criteria indicated that $15 \%$ of the age- 0 fish were mature, $82 \%$ of the age- 1 fish were mature, $97 \%$ of the age- 2 fish were mature, and $100 \%$ of the age 3 and older fish were mature. When the proportions of fish mature at length and age were estimated by logistic regression, median length at maturity ( $50^{\text {th }}$ percentile, $\mathrm{L}_{50}$ ) was estimated to be 34.7 cm for females, with the following proportions mature at age: age-0: 30\%, age-1: 68\%, age-2: 92\%, age-3: 98\%, and age-4: 100\%. Median age of maturity ( $50^{\text {th }}$ percentile, $\mathrm{A}_{50}$ ) was estimated to be about 0.5 years. Based on this new information, the 2000 SAW 31 (NEFSC 2000) re-considered the summer flounder maturity schedule for the assessment, but ultimately retained the maturity schedule for sexes combined as in the 1990 SAW 11 and subsequent assessments (rounded to $0.38,0.72,0.90,1.00,1.00$, and 1.00 as in the 1997 SAW 25 and 1999 assessment analyses).

In the 2005 SAW 41 work (NEFSC 2005), the maturity schedule was updated and broadened to include data from 1992-2004, covering the year range for individually measured and weighed fish sampled in NEFSC research surveys. The resulting sexes combined maturity schedule (age 0: 38\%; age 1: 91\%; age 2: 98\%; age 3+: 100\%) was retained in the 2006 assessment and 2006 NMFS Science and Technology reference point peer review (Terceiro 2006a,b).

The 2008 SAW 47 SDWG examined the proportions mature at age from 1982-1991 as well as the new NEFSC sampling protocol, individual fish information on length and age at maturity from 1992-2007. Using NEFSC fall survey maturity data from 1992-2007 and logistic regression, the median length at maturity ( $50^{\text {th }}$ percentile, $\mathrm{L}_{50}$ ) was estimated at 27.0 cm for males, 30.3 cm for females, and 27.6 cm for sexes combined. The median age of maturity ( $50^{\text {th }}$ percentile, $\mathrm{A}_{50}$ ) was determined to be 0.1 years for males, 0.4 years for females, and 0.2 years for sexes combined. These findings were consistent with the findings of the 1990 SAW 11, the URI 1999 study, the 2000 SAW 31, and the 2005 SAW 41. An examination of the proportions of mature age- 0 and age- 1 fish did not indicate any trend which would warrant modification of the maturity schedule, and so the 2008 SAW 47 concluded that it was appropriate to again retain the maturity schedule from the 2005 SAW 41 assessment (NEFSC 2008a). The 2005 SAW 41 combined sex maturity schedule was also retained in the subsequent 2009-2012 updated assessments (Terceiro 2012).

In work for the 2013 SAW 57 benchmark assessment (NEFSC 2013), McElroy et al. ( 2013 MS) produced a working paper detailing their examination of the sources of variability in summer flounder female maturity rates: whether they are dependent on method, or year, or both, and if so, to what magnitude. They compared at-sea and histological maturity assignments made during recent NEFSC resource surveys, and compared female maturity schedules derived from ovarian histology to those from earlier studies (noted above). McElroy et al. (2013 MS) studied

266 female summer flounder sampled during September through November of five years, 20082012, as part of the NEFSC fall bottom trawl survey. They also studied female summer flounder sampled as part of the Enhanced Biological Sampling of Fish (EBSF) project supported by the NEFSC, Northeast Cooperative Research Program (NEFSC-NCRP). A total of 935 mature females were collected either in monthly sampling from December 2009 to May 2011 or targeted sampling during the primary spawning season September to November (2011 and 2012) as well as March and April when spawning has also been reported (2012 and 2013 only). Catches were sampled from commercial vessels participating in the NEFSC-NCRP's Study Fleet or other NEFSC-NCRP research studies while fishing in southern New England waters (NMFS statistical areas 537, 539, and 611). These commercial fishery sampled data were used to aid in the interpretation of gonad histology; specifically, to identify the pattern and progression of oocyte maturation (reproductive seasonality).

McElroy et al. (2013 MS) concluded that "... at-sea assignments have a high rate of agreement with microscopic classifications (89\%). During this season, the majority of mature females were developing or even actively spawning; regenerating (spent) fish were rare. The largest of immature fish were difficult to classify correctly using macroscopic criteria, as some of these fish were preparing to spawn next year, for the first time; these fish were incorrectly classified at sea as resting, similar misclassifications have also been noted for winter flounder (McBride et al. 2013). An earlier study on summer flounder (NEFSC 2000) using gonad histology reported a similar misclassification rate between at-sea and histological assignments ( $13 \%$ vs. $11 \%$ in the current study). The non-matching maturity assignments were concentrated at the ages where the process of maturation was active (age 1 and age 2). Maturity in female summer flounder is rapid with $99 \%$ maturity achieved by age 4 , using either histology or macroscopic methods. Most of the errors were for immature fish identified as resting at sea. Removing the resting fish from the dataset improved the rate of agreement (95\%) between at-sea and histological classifications, and it resulted in overlapping CI’s for the maturity ogives between the classification methods. This may be one way to reduce observational error in the atsea maturity ogives. Otherwise, macroscopic classification remains an effective and cost efficient method for tracking female summer flounder maturity" and "The temporal trend using histology indicated that recently the declines in proportion mature at age for age 1 and age 2 fish were even greater than were evident in the macroscopic data, which are the ages with the most misclassifications."

McElroy et al. (2013 MS) found that most of the macroscopic classification errors were for immature females misclassified as resting ( T ) mature in the age $0-2$ range, which were actually 'IFM' fish - first time maturing females that likely would not effectively spawn until the next year. It is not clear that the same misclassification problem occurs for resting (T) males, as the maturity stage is less ambiguous in those fish. The new maturity analysis removed the resting (T) females from the NEFSC Fall survey 1982-2012 data. This action removed 1,866 resting females from the initial 11,073 fish (of both sexes), or $17 \%$ of the initial sample. This change, when maturities at ages are calculated for sexes combined, resulted in about an average decrease (unweighted average of annual maturities over the 1982-2012 series) in maturity of 4\% for age $0,2 \%$ for age 1 , and no change for ages 2 and older. The McElroy et al. ( 2013 MS) approach was adopted in compiling the maturities used in the 2013 SAW 57 benchmark assessment (NEFSC 2013).

Since the 2008 SAW 47 assessment, the NEFSC's general approach to the estimation of maturity schedules has advanced, mainly from work conducted for Northeast groundfish
assessments in 2008 and subsequent years (NEFSC 2008b, 2012). The new approach involves the evaluation of both observed and logistic regression estimated maturity schedules to look for periodicity and/or trends. Sometimes the number of samples taken for a given year, season, or sex is not sufficient for estimation, or the observed and estimated maturity shows high interannual variability due to small sample sizes, and so different year-bin combinations (e.g., annual, discrete multi-year blocks, multi-year moving windows, and time series) are examined.

For this benchmark assessment of summer flounder, the standard NEFSC fall trawl survey 1982-2016 ( 35 years) maturity data have been re-examined. The current data set consists of 7,887 males from age 0 to 15 and 6,297 females from age 0 to 14 , for a total of 14,184 fish. The 1982-2016 mean percent observed maturities at age (unweighted, simple arithmetic average of annual values at age) are $42 \%$ at age $0,95 \%$ at age $1,99 \%$ at age 2 , and $100 \%$ at ages 3 and older for males; $26 \%$ at age $0,83 \%$ at age $1,96 \%$ at age 2 , and $100 \%$ at ages 3 and older for females; and $36 \%$ at age $0,90 \%$ at age $1,98 \%$ at age 2 , and $100 \%$ at ages 3 and older for sexes combined (Figure A81). The time series value of L50\% was estimated to be 26.1 cm for males, 29.8 cm for females, and 27.0 cm for sexes combined (both). The A50\% was 0.13 years for males, 0.42 for females, and 0.23 years for sexes combined (i.e., fish about 13-17 months old, based on the actual spawning month and the January 1 ageing convention relative to fall sampling). The current L50\% and A50\% estimates and estimate maturity at age are comparable to those in previous assessments (Figure A82).

In keeping with the approach from the previous benchmark assessments (NEFSC 2008a, 2013), a sexes combined, three-year moving window ogive was compiled from the NEFSC 1982-2016 fall survey data for use in assessment models. The three-year moving window approach provides well-estimated proportions mature at age that transition smoothly over the course of the time series, while still reflecting any shorter term trends. The sexes combined, three-year moving window estimates are presented in Table A86 and Figure A83. The 19822016 mean maturities at age (unweighted, simple arithmetic average of annual values at age) are $29 \%$ at age $0,86 \%$ at age $1,99 \%$ at age 2 , and $100 \%$ at ages 3 and older.; these averages are $1 \%$ lower at age $0,2 \%$ lower at age 1 , and the same at ages 2 and older, compared to the 2013 SAW 57 values used in the 2013 and subsequent assessments. The most recent 5 year (2012-2016) mean values are $26 \%$ at age $0,75 \%$ at age 1, $97 \%$ at age 2 , and $100 \%$ at ages 3 and older.; these averages are the same at age $0,2 \%$ lower at age 1 , and the same at ages 2 and older, compared to the 2013 SAW 57 (2008-2012) values used in the 2013 and subsequent assessments.

## INSTANTANEOUS NATURAL MORTALITY RATE (M)

The instantaneous natural mortality rate (M) for summer flounder was assumed to be 0.2 in early summer flounder assessments (SAW 20; NEFSC 1996a). In the SAW 20 work, estimates of M were derived using methods described by a) Pauly (1980) using growth parameters derived from NCDMF age-length data and a mean annual bottom temperature $\left(17.5^{\circ} \mathrm{C}\right)$ from NC coastal waters, b) Hoenig (1983) using a maximum age for summer flounder of 15 years, and c) consideration of age structure expected in unexploited populations ( $5 \%$ rule, $3 / \mathrm{M}$ rule, e.g., Anthony 1982). The 1996 SAW 20 (NEFSC 1996) concluded that $\mathrm{M}=0.2$ was a reasonable value given the mean ( 0.23 ) and range ( $0.15-0.28$ ) obtained from the various analyses, and this value for M was used in all subsequent assessments until 2008.

For the 2008 SAW 47 assessment (NEFSC 2008a), longevity- and life-history based estimators of M were reviewed. Sex and age-specific estimates of M were calculated from 19762007 summer flounder age and growth data from the NEFSC trawl surveys. A summary of the
methods and conclusions from that work is provided here.
Longevity based estimators of M are sensitive to critical underlying assumptions which include the value of $p$, or the small proportion of the population surviving to a given maximum age, and the maximum observed age under no or low exploitation conditions. Using a maximum age of 15 years for summer flounder, and the methods of Hoenig (1983) and Hewitt and Hoenig (2005), longevity based estimates of M for combined sexes ranged from 0.20 to 0.36 depending on whether a $\mathrm{p}=1.5 \%$ or $\mathrm{p}=5 \%$ was assumed. Other life-history based approaches were used, including those from Pauly (1980), Jensen (1996), Gunderson and Dygert (1988), and Gunderson (1997), with resulting estimates ranging from 0.20 to 0.45 . Age-specific and size variable estimates of M, based on the work of Peterson and Wroblewski (1984), Chen and Watanabe (1989), Lorenzen (1996), and Lorenzen (2000), ranged from 0.19 to 0.90 , with the highest values associated with age 0-1 fish (fish at smaller lengths).

While the 2008 SAW 47 work provided a wide range of methods and $M$ estimates to be considered, each estimate involved a suite of underlying assumptions which were debated. In addition, the modeling frameworks of ADAPT virtual population analysis, ASAP statistical catch-at-age analysis, and Stock Synthesis Version 2 (SS2) statistical catch-at-age analysis used in the SAW 47 assessment allowed for log-likelihood profiling of M to determine which M estimate provided the best model fits. Based on an exercise using the base cases, the M that minimized the log-likelihood was $0.35,0.20$, and 0.25 under the models ADAPT, ASAP, and SS2, respectively. The estimate of M that resulted in the lowest residual or likelihood was found to be sensitive to model selection and configuration, as the data input configurations were very similar across the three models.

The 2008 SAW 47 considered the different methods of estimating M and after lengthy discussion assumed a natural mortality rate (M) of 0.20 for females and 0.30 for males, based mainly on recently observed maximum ages in the NEFSC survey data of 14 years ( 76 cm , in NEFSC Winter Survey 2005) for females and 12 years ( 63 cm , in NEFSC Spring Survey 2007) for males, and the expectation that larger and older fish are likely if fishing mortality rates were maintained at low rates in the future. A combined sex M-schedule at age was developed by assuming these initial M rates by sex, an initial proportion of females at age 0 of $40 \%$ derived from the NEFSC Fall survey indices by age and sex, and population abundance decline over time at the sex specific M rates. The final abundance weighted combined sex M-schedule at age ranged from 0.26 at age 0 to 0.24 at age 7+, with a mean of 0.25 (NEFSC 2008a). This Mschedule was retained in the subsequent 2009-2016 benchmark and updated assessments (NEFSC 2013; Terceiro 2012, 2015, 2016) and has been used in this benchmark assessment.

## SPATIAL DISTRIBUTION IN THE NEFSC TRAWL SURVEYS

A graphical examination of the Northeast Fisheries Science Center (NEFSC) 1968-2017 trawl survey data was conducted. The trawl survey sample data were examined in aggregate, for 'juveniles’ (fish < 30 cm ) and adults, and by sex. The data were (generally) aggregated into 5 year time intervals, and in some cases by geographical region. A full set of distribution maps is presented in Miller and Terceiro (2018b MS).

## Spring Aggregate

Plots of the spring (March-May) survey catches for multi-year time blocks reveal offshore aggregations of fish along the shelf edge that are caught during the early part of the spring survey (the southward March survey legs) and more inshore aggregations caught later (during the northward April survey legs). The earliest years showed the greatest presence of summer flounder in tows from inshore waters from Long Island to Cape Hatteras (Figure A84). These earlier time blocks through the 1990s, when the spring strata set for the early analytical assessments was developed, generally show only intermittent catches of summer flounder in the Georges Bank (GBK) region or in the Gulf of Maine (GOM). The lowest catch numbers in the time series were seen during the early 1990s just before increasing slowly in the late 1990s (Figure A85). During the rebuilding period of the 2000s, larger catches of summer flounder began appearing in Southern New England (SNE) waters, particularly south of Rhode Island and Massachusetts in offshore strata. More summer flounder were also present along the southern edge of GBK. A few small occurrences of summer flounder appear in tows in Massachusetts and Cape Cod Bays and around outer Cape Cod throughout the time series (Figure A86).

Spatial abundance trends for length data summarized by stratum are similar to the raw survey catch data referenced above, however these maps illustrate the spatial and temporal abundance in large versus small summer flounder, are summarized by stratum, and expanded by swept area. Across the entire time series, it is evident that smaller fish ( $<30 \mathrm{~cm}$, age 1 in the spring) are inhabiting areas in the southern range while fish in the northern range are nearly all $>30 \mathrm{~cm}$ (mainly age 2 and older). Summer flounder less than 30 cm tend to make up the majority of the catch in spring inshore strata south of the Chesapeake Bay. This is typical since juvenile summer flounder tend to remain inshore for the first year before migrating offshore the following winter. Over time, these southern strata, both inshore and offshore, begin to contain a greater proportion of large summer flounder (Figure A87-A90).

## Fall Aggregate

Plots of the fall (September-October) survey catches for multi-year time blocks reveal aggregations of fish mostly in inshore waters along the inner-half of the shelf and into the bays and estuaries. The earliest time block of 1968-1975 shows little or no catch of summer flounder on GBK or in the GOM. The second block of 1976-1980, however, shows more substantial catches over GBK and off SNE (Figure A91). Years of lower abundance (the early 1990s) show summer flounder aggregating more tightly in inshore strata while catches on GBK and of SNE declined (Figure A92). From RI waters to the southwest, most of the catches are confined to the inshore strata and the inner-most band of offshore strata. Abundance over time is similar to the spring with higher catches initially in the time series, dropping in the 1980s and 1990s. By the late 1990s, catches of summer flounder were highest in the southern range, especially surrounding the Chesapeake Bay area. During this rebuilding period, larger catches began occurring more frequently in the Mid-Atlantic Bight (MAB) and approaching SNE. An increased presence in central GBK and in Cape Cod Bay is also noticeable in later years of greater abundance (Figure A93).

Fall survey average annual minimum swept area abundances show an even more definitive line spatially dividing fish of sizes less than 30 cm (mainly ages 0 and 1 in the fall) and greater than 30 cm (ages 1 and older). Nearly all summer flounder caught north of Hudson

Canyon are >30 cm in size. Survey catches during the earliest years of the time series were focused around DelMarVa where the majority of the catch, particularly in inshore strata surrounding Delaware and Chesapeake Bay, were fish $<30 \mathrm{~cm}$ (Figures A94-A95). This divide appears to stretch further south during the rebuilding period during the late 1990s and early 2000s (Figure A96). Some smaller fish begin to re-enter catches north of Hudson Canyon as MAB and SNE strata become the new areas of greatest summer flounder abundance (Figure A97).

## Seasonal distributions by sex

At the broad regional scale of the NEFSC/MADMF spring and fall trawl survey sampling, there do not appear to be major differences in the distribution of summer flounder by sex. The distributions of the sexes seem to be about the same during the historical peak in abundance in the late 1970s (1975-1980), the historical low in abundance in the late 1980s (1986-1990), the most recent peak in abundance in the late 2000s (2006-2010), and in the most recent 5 years from 2011-2015 (Figures A98-A109).

However, finer scale studies suggest that there may be some difference in the timing of migration and distribution by season in inshore waters that are not yet well understood. A recent, small scale study in Rhode Island state waters has suggested that females were more prevalent in shallow waters $(\leq 15 \mathrm{~m})$ through all months sampled in a fishery independent survey, with males having greater presence in deeper waters (> 15 m ) from May through September (Langan et. al. 2018 MS). In addition, recent work examining fishery dependent data, such as Morson et al. (2012), identified a significant relationship between the sex ratio of recreational landings and the port at which summer flounder were collected, indicating that summer flounder exhibits some spatial sex segregation while inshore and during different seasons.

## Biomass and distributional trends

There is evidence that the spatial distribution of summer flounder has shifted and/or expanded over the last four decades. However, there are conflicting conclusions about the importance of potential drivers of the shift. A Vector Auto-regressive Spatio-Temporal (VAST) model was used to quantitatively investigate whether the distribution of the stock has shifted on the Northeast U.S. Shelf (NES) and the extent to which an observed shift can be explained by changes in abundance, size-structure, environmental variables, and fishing. The generalized linear mixed model (i.e., delta model) estimates the probability of summer flounder encounter and the magnitude of the catch biomass in survey samples as a function of the explanatory variables. Additional details are available in (Perretti 2018 MS).

Data from the NEFSC and NEAMAP spring and fall surveys were used. Model convergence statistics were met for both seasons, and residual plots did not suggest any significant model fit problems, although the model tended to under-predict the highest observations. Sensitivity analyses indicated that observed changes in the in center-of-gravity are unlikely to be due to changes in the spatial distribution of samples as the mean center-of-gravity or the higher observed catch rates in the NEAMAP survey.

A northward and eastward shift was observed in the center-of-gravity, with both recruits ( $<30 \mathrm{~cm}$ total length) and spawners at or near their historical maximum northing in recent years in both seasons (Figures A110-A113). Inclusion of NEAMAP data results in a more northerly
center-of-gravity in recent years although this difference was small in the fall model. Similarly, there has been an eastward shift in center-of-gravity in both size-groups and seasons with recent years at or near their historical maximum easterly. The inclusion of the NEAMAP data results in a more eastward shift in recent years. In the counterfactual analysis, the covariates explain relatively little of the variation in the center-of-gravity in either season or size-class.

Biomass trends within geographic subareas were also examined using 3 NES areas (Figure A114). Total biomass and proportion of biomass in each area and season are shown in Figures A115-A118. In both seasons the majority of recruit biomass is found in the southern area and that biomass has trended downward along with the shelf-wide recruit biomass. In recent years the proportion of recruits in the south has declined while the proportion in the middle area has increased. Spawner biomass is more evenly split between the middle and south regions, but similar to recruits, the proportion of spawner biomass in the south has declined as the proportions in the middle and northern areas have increased.

Similar to previous studies, this work indicated that summer flounder are shifting northeast over time, and this shift has continued in recent years. In contrast to previous studies, the distribution shift does not appear to be driven by an increase in the abundance of older, larger fish which tend to inhabit more northeastern waters. This is because the shift northward is evident even in small fish. Indeed, recruits appear to be shifting northward at a faster rate than spawners, suggesting they are not merely tracking the expansion of spawners northward. Instead, they appear to be reacting to some other driver. The northward shift of recruits also suggests that the driver is unlikely to be fishing as recruits are relatively lightly exploited by the fishery. However, neither total biomass nor environmental covariates explain the distribution shift. Instead, most of the distribution shift is attributed to unexplained sources. Additional work is needed to further explore this approach and possible covariates through VAST.

In addition to the VAST work, some preliminary analyses have been done using Conditional Autoregressive (CAR) models and the Integrated Nested Laplace Approximation (RINLA) approaches to examine the spatial distribution of summer flounder and its relationship to ecological covariates (Deen et al. 2018 MS). Results suggest that the distribution of summer flounder stock is correlated with depth, salinity and regional climate-driven increases in ocean temperature. Additional work is needed to further explore this approach.

## Ecosystem Context

Additional contextual ecosystem information was developed for this assessment. Data extractions for spring and fall are confined to the summer flounder stock area based on current survey strata sets. Several aspects of the ecosystem seem to be changing in the most recent years. Fall bottom and surface temperature are increasing and salinity is at or near the historical high levels. These physical series may have shifted around 2012, the warmest year on record for this ecosystem. Spring chlorophyll concentrations, a measure of bottom-up ecosystem production in the summer flounder stock area, are variable, but the fall time series is decreasing, especially so over the period 2013-2017. Spring abundances for key zooplankton prey are variable and may be worth examining alongside recruitment patterns, an issue for future research. Both probability of occurrence and modeled habitat area show similar patterns of increases from the 1990s to the present, which suggests despite reduced abundance in the past five years, the distribution footprint of summer flounder has not contracted. These Ecosystem Context indicators, and methods to develop them, can be found at:
https://www.nefsc.noaa.gov/ExternalDrive/drives/SummerFlounder2018/Sept2018Meeti ng/friedland_ecosystem_context/ECSA_summer-flounder.html

## Conclusions

There are apparent changes in spatial distribution of summer flounder over the last four decades with a general shift northward and eastward. Spatial expansion is more apparent in the years of greater abundance since about 2000, although it has continued even with the most recent declines in biomass. Higher levels of exploitation can lead to reduced heterogeneity in age structure, particularly a reduction in the abundance of older age fish. However, work examining recent shifts in recruits and an examination of other ecosystem factors suggests other mechanisms may also be contributing factors.

The impact of the change in distribution on summer flounder stock productivity is important but difficult to determine. Although recruitment has been relatively low in recent years, the driver of these low recruitment events has not been identified. Attempts to link specific covariates to changes in the spatial distribution of recruits did not uncover a clear driving variable. Many factors may be impacting the productivity of the stock and identifying the mechanisms driving these observed changes warrants further research. The use of recent weight-at-age and maturity-at-age information in the biological reference point estimates (TOR 5) and in catch projections (TOR 7) attempts to integrate the effects of these factors on the future productivity of the stock.

TOR A4. Estimate annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series, and estimate their uncertainty. Include retrospective analyses (both historical and within-model) to allow a comparison with previous assessment results and projections, and to examine model fit. Examine sensitivity of model results to changes in re-estimated recreational data.

## 2018 MODEL DEVELOPMENT

## Background

Fishing mortality rates and stock sizes were estimated using the ASAP statistical catch at age model (Legault and Restrepo 1998, NFT 2012a, b, 2016). ASAP is an age-structured model that uses forward computations assuming the separability of fishing mortality into year and age components to estimate population sizes given observed catches, catch-at-age, and indices of abundance. The separability assumption is partially relaxed by allowing for fleet-specific computations and by allowing the selectivity-at-age to change in blocks of time. Weights (lambdas [L], or emphasis factors) are input for different components of the objective function which allows for configurations ranging from relatively simple age-structured production models to fully parameterized statistical catch-at-age models. The objective function is the sum of the negative log-likelihood of the fit to various model components. Catch at age and survey at age compositions are modeled assuming a multinomial distribution, while the other model components are assumed to have lognormal error. Specifically, lognormal error distributions were assumed for the total catch in weight, research survey aggregate indices, selectivity parameters, annual fishing mortality parameters, survey catchability parameters, estimated stock numbers at age, and Beverton-Holt stock-recruitment parameters (Beverton and Holt 1957), when estimated. Recruitment deviations are also assumed to follow a lognormal distribution, with annual deviations estimated as a bounded vector to force them to sum to zero (this centers the predictions on the expected stock-recruitment relationship).

The 2013 SAW 57 benchmark assessment model (NEFSC 2013) differed from the previous 2008 SAW 47 ASAP model (NEFSC 2008a) only in the setting of the fleet Effective Sample Size (ESS) and two Stock-Recruitment (S-R) function priors which were set to zero. The 2008 SAW 47 assessment process had considered models with two, four, and six fishery fleet configurations. Differences between the two and four fleet models were relatively minor, but convergence problems were encountered for some configurations of the six fleet model. The 2013 SAW 57 model included two fleets, one for fishery landings and one for fishery discards.

The fishery selectivity models for both landings and discards used an 'estimates-at-age' approach, wherein at least one age is fixed with selection $(S)=1$ and other selectivities at age are estimated relative to the reference age or ages. The references ages were age 3 (model age 4) in the first landings time block (1982-1994), age 4 (model age 5) in the second landings time block (1995-2007), and also at age 4 (model age 5) in the third landings time block (2008-2012). The reference ages were age 1 in the first discard time blocks and 2 in the second and third discard time blocks. These selectivities were set with $L=1$ and Coefficient of Variation (CV) set to 0.50 , in effect specifying priors on the initial values that were components of the objective function.

The fishery-independent research survey indices used for model calibration are configured as aggregate indices (in numbers) with associated age compositions modeled as
proportions that follow the multinomial distribution. Each aggregate index has a specified input CV and the associated age composition has the 'estimates-at-age' selection pattern either estimated (for surveys with several ages) or fixed = 1 (for single age, young-of-the-year [YOY] age 0 surveys). Survey catchabilities (q) and selectivities (S) were set with $L=0$ and so were not a component of the objective function. The CV on the different survey qs were initially set at an average value of the empirical sampling CVs, and later sometimes adjusted or 'tuned' in an attempt to improved model diagnostics.

Other 2013 SAW 57 model details included:

1) fishery landings and discard 'fleet' catches $L$ set at 1 and $C V=0.1$,
2) landings fleet age composition Effective Sample Size (ESS) = 55 and discards fleet age composition ESS = 30, following initial runs and consideration of suggested Francis (2011) ESS and the median estimated ESS,
3) fishing mortality ( F ) and stock size ( N ) in year $1 \mathrm{CVs}=1.0$ and $\mathrm{Ls}=0$, and
4) Stock-Recruitment (S-R) function and population scaler Ls were set to 0 , effectively 'turning off' the influence of the S-R function in the model objective function by setting those likelihood components to zero. The recruitment deviations L was also equal to 0 , and so also were not part of the objective function, allowing recruitment deviations to be estimated from the fishery and survey data without any prior constraint.

In the 2013 SAW 57 ASAP model age-specific instantaneous natural mortality rates providing an average $\mathrm{M}=0.25$ were assumed for all years. Seasonal survey indices and all survey recruitment (age-0) indices were compared to population numbers of the same age at the appropriate season of the same year. All model inputs were set at consensus values by the 2013 SDWG after multiple sensitivity runs to evaluate a range of inputs (NEFSC 2013).

## Existing 2013 SAW 57 Benchmark ASAP Model Updated through 2017: model run F2018

The existing 2013 SAW 57 benchmark ASAP model was updated with data through 2017 in response to TORs 4 and 6a. The 2013 SAW 57 benchmark model settings were generally retained through the 2015 and 2016 assessment updates (Terceiro 2015, 2016), and fishery and survey catches updated through 2017, in updating the existing model, now named 'F2018.’ The third fishery selection time block was extended from 2008-2012 to 2008-2017. The fishery landings and discard ESS values of 55 and 30 and the various survey input CVs were retained.

A few minor changes to model settings were made over the course of the transition from the 2013 SAW57 benchmark through the 2015 and 2016 assessment updates to the current model (F2018), based on experience and recommendations from other Northeast assessment during the intervening period. These included: 1) discontinued use of 'likelihood constants,' which to date in Northeast data-rich stock assessments had been found to mainly affect the manner in which recruitment deviations are constrained, 2) a minor change to the initial F , initial N , and recruitment CVs, increasing them from 0.9 to 1.0 for consistency with other initial parameter settings, and 3) recruitment deviations $L$ set to 1 with $C V=1.0$, to prevent the estimation of one extremely large cohort while allowing recruitment deviations to be estimated from the fishery and survey data with minimal prior constraint.

## Model Fit Diagnostics

Most of the likelihood contribution to the model fit was due to the age compositions,
owing to the large number of fishery and survey catch-at-age estimates that are made. The Root Mean Square Error (RMSE) for the aggregate survey indices were all close to or inside the expected 95\% confidence for RMSE (NFT 2012b) except for the MADMF YOY index, which was still well outside the confidence interval even with the input CV increased to 1.0. The aggregate landings and discards and age composition fit diagnostics and residuals did not reveal any serious problems, although some trends and isolated large residuals for some surveys were evident. Otherwise, there were no major diagnostic problems with the F2018 model run. The model fit the fishery data well, and most of the observed survey indices were within the $95 \%$ confidence interval ( $<=2$ standardized residuals) of the model estimates.

Some of the 'worst' fitting indices, with more than a single standardized residual >> 2, were:

1) MAS - MA Spring trawl survey
2) RIF - RI Fall trawl survey
3) CTS - CT Spring trawl survey
4) MAYOY - MA seine survey YOY
5) DEESYOY - DE Estuaries survey YOY
6) DEIBYOY - DE Inland Bays survey YOY
7) MDYOY - MD ocean-side estuary survey YOY
8) URIGSO - URI Graduate School of Oceanography Narragansett Bay 2-station survey

A few of the surveys also demonstrated potentially concerning patterning of the residuals, including:

1) DEIBYOY
2) ChesMMAP - VIMS Chesapeake Bay multispecies survey
3) NEAMAP Fall - VIMS ‘inshore strata’ coastal trawl survey
4) URIGSO

The SFWG concluded that these latter four indices might be candidates for further 'downweighting' though further inflation of their input CV (which would also likely worsen the size of the largest residuals) or exclusion in subsequent model development. The F2018 model run results are briefly described in the next section and an evaluation of stock status relative to the 2013 SAW 57 biological reference points is presented under TOR 6a.

## Retrospective and MCMC Analyses

An 'internal' retrospective analysis for the F2018 run was conducted to examine the stability of the model estimates as data were removed from the end of the time series. Seven retrospective runs ('peels') were made for terminal years back to 2010. The summer flounder stock assessment has historically exhibited a retrospective pattern of underestimation of F and overestimation of SSB; the causes of this previous pattern have not been determined. Over the terminal 7 years, the F2018 model run annual retrospective change (Mohn’s rho; error) in fishing mortality ( F ) averaged $-15 \%$ and ranged from $-31 \%$ in 2012 to $<-2 \%$ in 2015 . The annual retrospective change in SSB averaged $+12 \%$ and ranged from $+7 \%$ in 2015 to $+25 \%$ 2012. The annual retrospective change in recruitment (true age 0 , model age 1 ) averaged $+17 \%$ and ranged
from <-1\% in 2016 to $+43 \%$ in 2012 (Figures A119-A121). The F2018 model run point estimates of instantaneous fishing mortality (F; fully recruited at model age 5, true age 4) and Spawning Stock Biomass (SSB) in 2017 were 0.244 and $34,350 \mathrm{mt}$. The retrospectively adjusted estimates were 0.287 and $30,670 \mathrm{mt}$.

A Markov Chain Monte Carlo (MCMC) run of the F2018 model was made to evaluate the precision of the estimates and help judge the magnitude of the retrospective pattern. One million MCMC iterations were made, of which one thousand were saved, that provided median F in 2017 of 0.236 , with a $90 \%$ confidence interval (CI) from 0.191 to 0.293 . The median SSB in 2017 was estimated to be $34,873 \mathrm{mt}$, with a $90 \%$ confidence interval (CI) from $30,533 \mathrm{mt}$ to $39,800 \mathrm{mt}$. Given recent standard procedures for Northeast stock assessments that use complex age-structured population models (e.g., NEFSC [2013] for summer flounder and NEFSC [2017] for New England groundfish), because the retrospectively adjusted terminal year estimates fall within the $90 \%$ CI for both F and SSB, the F2018 model run would be considered to have a minor retrospective pattern, with no adjustment to the terminal year estimates needed to evaluate stock status or conduct projections.

## 2018 SAW-66 Model Comparison Workshops

## Model Comparison Workshop \#1

An initial model comparison workshop was held during January 30-February 1, 2018 to examine multiple modeling approaches under consideration for use in the 2018 SAW-66 stock assessment. Overall the first model workshop:

1) Agreed to schedule another model comparison workshop between the end of April and early June
2) Developed strategies for both self-testing and cross-testing the assessment models
3) Identified additional analyses to be completed prior to the next SAW meeting for all assessment models and the VAST model to address TOR 4
4) Agreed to conduct exploratory work to aggregate non-federal survey data
5) Concluded that modeling should start simple, and that complexity (e.g. sex, time varying growth, etc.) should be built into the models given constraints of the data, estimation, and diagnostics results
6) Determined that estimation problems, precision degradation, and diagnostic problems (e.g. residuals and profiles) should be used to guide decisions
7) Will examine modeling approaches to help understand changes in recruitment, distribution, and other regime shifts.

The first model workshop also agreed to the assumptions and settings for the input data and configurations and for potential future work for the population models under consideration, including:

## Biological

Retain the Lux and Porter (1966) commercial fishery quarterly length-weight parameters (combined sexes)

Use the 2013 SAW 57 three-year moving window method for calculating maturities, updated with data through 2016 (no fall 2017 maturity data is or will be available) Retain the 2013 SAW 57 values assumed for natural mortality (M) in model development (i.e., $M=0.3$ males, $M=0.2$ for females (average $=0.25$ ))

## Surveys

Use NEFSC surveys only for across model comparison
Model the NEFSC surveys separately: Albatross (ALB) and Bigelow (BIG, BIGSWAN)
NEFSC BIG surveys incorporating sweep study results
Explore sensitivity to survey data weighting specifications
Explore inclusion of other non-federal surveys where possible
Agreed to conduct exploratory work to aggregate non-federal survey data (e.g.
GLM and/or other approaches will be considered)
Examine the effect of allowing q's for problematic surveys to vary (e.g. the "problematic" 4)
Examine the effects of the starting year of data - should the survey year be the first year in the model?

## Fleets

Use the four-fleet configuration (i.e., commercial landings, commercial discards, recreational landings, and recreational discards) in model development Selectivity:

Explore the fishery selectivity for all fleets including specifications that allow doming, force flat top, and use different not estimated (fixed) ages
Explore the specification for the fishery selectivity blocks to identify breakpoints over the time series
Consider changes in size at age
Consider regulatory changes
Consider other informative empirical data
Explore sensitivity to fleet data weighting specifications
Examine the effects of the starting year - should the start of the fleet data be the first year in the model?
Determine how to address the proportion of females at age in the fleets
Obtain data for specific years from Rutgers and NEAMAP
Examine tagging the data on the end or using approaches to hindcast
Compare the ratio of the sex at age from these studies with the survey sex at age
Additional Potential Exploratory Work
Examine the autocorrelation in R
Estimate M within the model, or profile over M
R0 profiling
Examine production model diagnostics
BRPs - not internally estimable at this time; will need to examine proxy approaches
Residual analyses

Individual Modeling Work (In Addition to the Above)
ASAP
Combined sex modeling work (see completed working papers)
Explore by sex models (see above)
SAL
Modeling growth (various approaches)
Incorporate seasonal effects, if enough data to support
Examine different time blocks for selectivity at length
Explore how to better model the selectivity by sex
Incorporate an aging error matrix if possible (not high priority for additional work)
State-space
Specify the selectivity by sex
Estimate M within the model
VAST
Incorporate environmental variables into the model
Incorporate non-federal survey data, for which spatial effects can be estimated Test if observed if changes in distribution seen are due to changes in the sampling locations, by assigning a catch of 1 to each observation and determining if the center of gravity changes
Examine the differences in spatial effects by sex (for samples that have sex available)
Compare the VAST output to a design-based estimate

## Model Comparison Workshop \#2

A second model comparison workshop was held during May 29-31, 2018 to again examine multiple modeling approaches under consideration for use in the 2018 SAW-66 stock assessment. The second workshop made two overall recommendations:

1) The combined sex, Age Structured Assessment Program (ASAP) was identified as the primary assessment model for the following reasons:

The selected model has been used for other stocks in the region and has the necessary components and diagnostics developed for presentation to the stock assessment review committee (SARC), and to provide summer flounder science to support management

There were not strong differences in model outputs (i.e., trends in SSB, F, R) between those models that incorporated additional sex-specific complexity and those that did not; therefore, gains from the additional sex-specific information were not shown, and did not warrant selection of a less developed model that required additional parameters and assumptions

Incorporating the revised Marine Recreational Information Program (MRIP) information
will require substantial model diagnostic capability, and ASAP has those diagnostics fully developed

The models not selected as primary required further development and exploratory work to allow the SAW WG to determine that those models are complete and performing at the level of SARC standards

Other proposed model outputs can be treated as secondary, informative models, and will still contribute substantially to the assessment in a supportive manner
2) The workshop agreed that updated information (i.e., 2017-2018 and revised MRIP) should be incorporated into the primary assessment model. Incorporating updated data into supportive models is a lower priority and is secondary to other modeling tasks needed to further develop those secondary models.

The workshop also made recommendations for ongoing work for the primary ASAP model to be included as part of the assessment, to be completed prior to the fall 2018 Data/Model meeting.

ASAP (combined sex)
Update model with most recent fishery dependent and independent information, including any revised MRIP estimates
Explore the sensitivity of the time blocks used for selectivity for all the fleets
Consider commercial discard selectivity as two time-blocks versus the present configuration of three
Examine the sensitivity of the doming in the landings fleets
Explore inclusion of non-federal surveys under various configurations
Include the surveys as individual indices with length compositions
Consider hierarchical analysis to combine indices:
Combine the young-of-year (YOY) indices only; treat age1+ as individual indices Combine by age vector (YOY, age $1+$ ) and/or by season
Use principal components analysis to do a priori bundling of indices (lower priority for work)
Develop methods for applying length compositions to combined indices
Obtain raw data needed from state agencies to develop empirical estimates of uncertainty Explore influence of the priors selected

## Supportive Assessment Models (ongoing work)

The following describes some specific ongoing work recommended by the SFWG for the supportive and informative models that will be included as part of this assessment, to be completed prior to the fall Data/Model meeting.

Overall

Working paper(s) will be developed by SFWG members that explore how sex-specific models might inform biological reference point development

ASAP (by sex)
Update model to match base case for primary model
SAL (sex-at-length)
Review data inputs to ensure units correctly specified and length frequencies correctly applied
Integrate calculations for spawning stock biomass
Incorporate selectivity time blocks (i.e., starting in 1982, 1995, and 2008)
Develop methods to produce short term forecasts for use in management
Complete a simulation self-test for the model
Update with recent data after additional model development/diagnostics have been completed (lower priority for work)

State-space
Examine scale shift resulting from specification of four fleets versus two
Explore sensitivity of the doming in the landings fleets
Complete additional work to fine tune selectivity
Incorporate selectivity time blocks
Develop methods to produce short term forecasts for use in management Complete simulation self-test for the model
Update with recent data after additional model development/diagnostics have been completed (lower priority for work)

Stock Synthesis (externally submitted working paper)
M. Maunder - "Stock Synthesis Implementation of a Sex-Structured Virtual Population Analysis Applied to Summer Flounder"
This paper was intended to inform model considerations
Information from the current or an updated version of this working paper will be incorporated in the assessment report and referenced as supportive modeling work

## Other Modeling/Analytical Work (ongoing)

The following describes other ongoing work recommended by the workshop, to address aspects of the stock assessment terms of reference.

VAST

Explore the abundance/biomass scaling issue for the spring and fall
Examine if the NEAMAP data (shorter, recent time-series) is causing the observed shift in abundance/biomass distribution in recent years Consider additional bottom temperature fields and other indicators of secondary productivity
Review whether the day/night sampling is creating issues for the NEAMAP and NEC calibrations
If data are sufficient, examine changes in abundance/biomass distributions by sex Explore the survey time series by region (e.g., North, South, etc.) to determine if observed northward shift is due to increases in North, decreases in South, or both If possible, consider whether annual VAST outputs could inform the selectivity block choices in other models

Phenology Work (externally submitted working paper)
J. Langan et al. - "Characterizing Changing Summer Flounder Phenology in Response to climate in a Large Temperate Estuary"
This paper was intended to inform ecosystem considerations
Information from the current or an updated version of this working paper will be incorporated in the assessment report and referenced as supportive work

## Habitat Suitability Modeling

Consider this work if submitted as a future working paper
Plan-B
Explore index and catch based approaches to specifying catch limits
If possible, examine whether VAST modeling work could provide inputs to some of these data limited approaches

## ASAP Model Building: F2018 model with Four Fleets

As noted above, previous benchmarks have considered ASAP model configurations with more than two fleets, but settled on two - aggregate landings and aggregate discards - as the best compromise between complexity and precision. Over the past few years, however, Northeast U.S. management agencies have implemented regimes that contain Accountability Measures (AMs) by fishery and catch type. Therefore, there has been recent interest in structuring Northeast U.S. assessment models to be better able to monitor the corresponding fishery components, as well as the potential to more accurately model fishery selectivity. To that end, the F2018 model was modified to have 4 input fleets (F2018_4FLEET): commercial landings and discards and recreational landings and discards. This is also reflective of the basis on which the input aggregate catch and catch at age is compiled.

To accommodate the four fleets, the ESS for both landings fleets was initially set at 50 and the discards fleets at 30. Ages with full selection were initially set in line with the two fleet model for three time blocks (1982-1994, 1995-2007, 2008-2017), with $S=1$ for age true ages 2,

3 , and 4 (model ages $3,4,5$ ) for the landings fleets and true ages 1,2 , and 2 (model ages $2,3,3$ ) for the discards fleets.

The initial run fit the fishery catch data well. The largest fleet catch residuals were for the commercial landings, but the largest standardized residual was less than 1.4. All fleet fits exhibited multi-year runs of residuals, the largest being nine years for both landings fleets in the late 1990s-early 2000s (observed catch smaller than estimated) and 10-11 years in the discard fleets after 2005 (observed catch larger than expected), but the standardized residuals were generally less than 0.5 . Therefore, none of the catch residual patterns were of major concern. Fits to the survey aggregate and catch at age indices were very similar to the two fleet model fits.

After an initial F2018_4FLEET run the input ESS was adjusted, based on the time series patterns and medians of the estimated ESS, to $75,35,60$, and 60 . In the initial run the first commercial discards period exhibited an uneven pattern suggesting that $S=1$ should be set on true age 2 , rather than age 1 , so that setting was also changed.

In the second 'adjusted' run, the first commercial landings period continued to exhibit an uneven pattern and large decrease in selection at true ages $5-7+$ to less than 0.4 , estimates that that cannot be justified from the known characteristics of the fishery. However, the precision of these estimates was acceptable, with CVs from 0.22 to 0.33 . The third period commercial landings selection also exhibited at large drop for true ages 6 to $7+$ from $S=1.0$ to $S=0.60$, but with good precision of the true age $7+$ estimate of $\mathrm{CV}=0.19$.

Time series trends in F, SSB, recruitment (model age 1, true age 0 ), and plus group stock size (model age 8+, true age 7+) for the two fleet (F2018) and four fleet (F2018_4FLEET) models are similar, but differed substantially in absolute magnitude, particularly for the SSB and plus group estimates since about 2000 (Figures A122-A123). Fits to the aggregate survey indices were very similar. Most of the difference was attributable to the differences in estimated fishery selectivity, with the four fleet model estimating more strongly domed selection patterns for the two landings fleets (which generally account for $80-90 \%$ of the total catch), which then resulted in larger estimates of stock size for the oldest ages and the SSB. As noted above, low selection at the oldest ages is hard to justify given the known characteristics of the fishery, but the statistical diagnostics of those estimates were acceptable, with CVs generally in the 0.20 to 0.40 range.

A comparison of the two fleet and four fleet model retrospective analyses (table below) indicated that the four fleet model generally had larger retrospective errors (value of Mohn's rho averaged over 7-year peels) for Full F and SSB; while results at-age were variable; the four fleet errors at age were also generally larger (7 of the 8 ages).

| Estimate | F2018 (2 fleets) | F2018_4FLEET |
| :---: | :---: | :---: |
|  |  |  |
| Full F | $-15 \%$ | $-19 \%$ |
| SSB | $+12 \%$ | $+15 \%$ |
| Total Stock Size N | $+8 \%$ | $+5 \%$ |
| Age 0 N | $+16 \%$ | $+5 \%$ |
| Age 1 N | $+3 \%$ | $-5 \%$ |
| Age 2 N | $-2 \%$ | $-4 \%$ |
| Age 3 N | $+3 \%$ | $+4 \%$ |
| Age 4 N | $+9 \%$ | $+12 \%$ |
| Age 5 N | $+15 \%$ | $+22 \%$ |
| Age 6 N | $+19 \%$ | $+30 \%$ |
| Age 7+ N | $+25 \%$ | $+35 \%$ |

## ASAP Model Building: F2018 with split NEFSC trawls survey series; ALB and BIG indices

The NEFSC winter (1992-2007), spring (1982-2017) and fall (1982-2016) bottom trawl surveys are among the research survey time series used to calibrate the current F2018 ASAP population model. The surveys were conducted using the FSV Albatross IV (ALB; with some intermittent substitution of the FSV Delaware II) until 2008 and the FSV Henry B. Bigelow (BIG) since 2009. A change in nets and towing protocol for the BIG resulted in potential changes in catchability for the spring and fall surveys, and several hundred comparison tows were made during 2008-2009 (both during the regular survey work and on special cruises) to develop calibration coefficients on aggregate number, aggregate weight, and on number at length bases to allow conversion of the BIG survey indices to ALB equivalents (Miller et al. 2010). The current (existing) F2018 (2 fleets) assessment model uses the NEFSC spring and fall ALB equivalent survey catch in relative aggregate numbers and numbers at age index forms.

A model run (F2018_BIGSV) was configured with separate spring and fall ALB (19822008) and BIG (2009-2017) time series of relative indices (i.e. stratified mean number per tow at age and in aggregate). All other model input data and settings remained the same as in the F2018 (2 fleets) run. Evaluation of the NEFSC spring and fall catchability coefficient (q) estimates for these relative indices of abundance provides a diagnostic of model uncertainty due to the use of the calibration factors, by comparison of the resulting ratio of BIG to ALB estimated $q$ with the calibration factors.

Industry cooperative 'twin trawl sweep study' cruises were conducted during 2015-2017 in an attempt to better understand the behavior and performance of the BIG survey gear for a suite of bottom-tending species, including summer flounder. Preliminary results (T. Miller NEFSC personal communication 2017) from analyses of those data indicate that the average catch efficiency of the BIG gear for summer flounder is about 0.56 (i.e., $56 \%$ of the summer flounder encountered by the BIG gear are retained by the net). Averaged over day and night tows, the BIG catch efficiency is about 0.02 at 15 cm , increases to $0.50-0.60$ from 32 cm to 60 cm , and increases further to 0.95 at 77 cm .

The 'sweep study' work also indicates that herding of fish by the BIG ground cables (wire between the wing end of the net and the trawl doors) and the trawl doors gear is likely to be low, and so the wing spread of the BIG gear ( 39.4 feet $=12.0$ meters) is considered the
appropriate dimension to use for swept area calculations. The current standard BIG area swept per tow is 0.00647931 square nautical miles (sqnm). The average values of BIG efficiency at length were first used to convert 'standard' catch per tow (Table A49) to 'absolute' catch per tow (Table A50). Next, the net dimensions and the annual spring and fall total survey coverage area (usually about 27,855 sqnm for the spring and 17,924 sqnm for the fall) were used to compute BIG indices as Swept Area Numbers (SWAN), or absolute estimates of stock numbers at age and in aggregate (Tables A51-A52). These estimates were used in another run, F2018_BIGSWAN, to further evaluate the catchability coefficients estimated for the NEFSC spring and fall surveys and as a diagnostic for the 'scaling' of the model stock size estimates, with the expectation that on the absolute scale, the q estimates are expected be less than or equal to 1 .

A comparison of the NEFSC surveys estimated qs and ratios of interest for the F2018, F2018_BIGSV, and F2018_BIGSWAN runs are presented in the table below.

| Survey | F2018 | F2018_BIGSV | F2018_BIGSWAN |
| :--- | ---: | ---: | ---: |
| NEC_SPR_ALB | $4.519 \mathrm{e}-5$ | $4.177 \mathrm{e}-5$ | $4.177 \mathrm{e}-5$ |
| NEC_SPR_BIG | - | $10.010 \mathrm{e}-5$ | $0.649 \mathrm{e}+0$ |
| NEC_FAL_ALB | $6.052 \mathrm{e}-5$ | $5.924 \mathrm{e}-5$ | $5.924 \mathrm{e}-5$ |
| NEC_FAL_BIG | - | $11.732 \mathrm{e}-5$ | $0.484 \mathrm{e}+0$ |
|  |  |  |  |
| Ratio SPR BIG/ALB qs |  | 2.396 |  |
| Ratio FAL BIG/ALB qs |  | 1.980 |  |
| Mean BIG/ALB qs |  | $\mathbf{2 . 1 8 8}$ |  |
|  |  |  |  |
| SPR Calib Factor |  | 1.897 |  |
| FAL Calib Factor |  | 1.911 |  |
| Mean Calib Factor |  | $\mathbf{1 . 9 0 4}$ |  |

The mean of the F2018_BIGSV run NEFSC spring and fall survey ALB and BIG qs is about 2.2. The mean of the spring and fall length-based calibration factors used to convert the BIG indices into ALB equivalents for the indices used in the current F2018 model is about 1.9. Therefore, the F2018_BIGSV qualitatively returns the same BIG to ALB catch ratio (i.e., numeric calibration factor of about 2) as the calibration experiment factor. Figures A124-A125 compare some results from the F2018 and F2018_BIGSV runs. The F estimates are very similar. The SSB estimates are generally slightly higher for the F2018_BIGSV run since about 2000. Most of the SSB difference is due to higher stock size estimates at the older ages. The estimates at model age 1 (recruitment at true age 0 ) are very similar, while the largest differences occur for model age 8+ (true age 7+) since 2000.

As noted in TOR 2, application of the experimental 'sweep study' BIG efficiencies at length changes the computed catch per tow of the indices and, for the fall numeric indices, changes the rank order of the annual indices (i.e., 2016 is the highest in the 2019-2017 series; Figures A27-A28), so the BIG indices in the F2018_BIGSWAN run are slightly different than those in the F2018_BIGSV run. Therefore, the F2018_BIGSV and F2018_BIGSWAN configurations do have minor differences in their results.

The NEFSC BIG trawl survey absolute abundance estimates used in the F2018_BIGSWAN run are dependent not only on the results and assumptions from the twin trawl sweep study, but also those assumptions included in the expansion calculations (i.e., trawl wing swept area, no door herding, no escape about the head rope, sufficient sampling to assume the survey index is applicable to the entire survey area, etc.). The resulting q estimates from the BIGSWAN run (mean $=(0.649+0.484) / 2)=0.567$; see text table above) indicate that for this particular model configuration the NEFSC BIG trawl surveys on average 'count' about $60 \%$ of the total stock numbers.

## ASAP Model Building: F2018 with Four Fleets and BIGSWAN indices

The next step in ASAP model building was to combine the effects of changing from two fishery catch fleets to four fleets with changing from all NEFSC ALB indices to 'splitting' the ALB and BIG index series. Figures A126-A127 compare the results for the F2018 (two fleets), F2018_4FLEET, and F2018_4FLEET_BIGSWAN model configurations. The plots demonstrate that the larger effect is due to changing from two fleets to four fleets. The 'splitting' of the NEFSC survey series and incorporation of the sweep study BIG efficiency estimates have a moderating effect on the fleet configuration change, with less 'doming' in the older ages for the landed fleets resulting in a smaller increase in SSB (Figure A126) and older age stock sizes (Figure A127). The trends are the same across the three configurations, with the F2018_4FLEET_BIGSWAN model estimates 'intermediate’ in scale compared to the F2018 (two fleets) and F2018_4FLEET results, although closer to the F2018 results.

In the F2018_4FLEET_BIGSWAN run, there are no issues of major concern with magnitude or pattern for the model fits to the four fleet aggregate catches. For the commercial landings, there is a single log-scale standardized residual larger than 1.5 (1995) and no unusual patterns. There is some blocking (long run during 2005-2015) of positive residuals for the recreational discards (fleet 4), but the log-scale standardized residuals are all small, generally at less than 0.30 . The fits to the fleet age compositions are all generally good, with the largest absolute residuals occurring for the recreational discards, with a few proportional differences of about 0.3 during the late 1990s. The SFWG noted that the ESSs could be adjusted to better approach the median value (in line with most recent standard ASAP procedures for the EFF settings), but that potential adjustment was delayed until the final catches (i.e., calibrated 'New' MRIP recreational catch) were available.

The same surveys that most demonstrated some residual problems (magnitude and patterning) in the current F2018 model (2 fleets, ALB indices) also did so in the F2018_4FLEET_BIGSWAN configuration, namely:

1) DEIBYOY - DE Inland Bays survey YOY
2) ChesMMAP - VIMS Chesapeake Bay multispecies survey
3) NEAMAP Fall - VIMS ‘inshore strata’ coastal trawl survey
4) URIGSO - URI Graduate School of Oceanography Narragansett Bay 2 station survey

These indices still seem the most likely candidates for further 'down-weighting' though further inflation of their input CV (which would also likely worsen the size of the largest
residuals) or exclusion from the model going forward.
A seven-year peel retrospective analysis F2018_4FLEET_BIGSWAN was run to further evaluate model diagnostics. The average retrospective error for F was $-15 \%$, the average error for SSB was $+13 \%$, the error for Total stock size N was $+5 \%$, and the errors for stock size N ranged from $-2 \%$ for model age 2 (true age 1 ) to +35 for model age $8+$ (true age $7+$ ). These retrospective errors are about the same as for the F2018_4FLEET model configuration (see table below).

| Estimate | F2018 (2 fleets) | F2018_4FLEET | F2018_4FLEET_BIGSWAN |
| :---: | :---: | :---: | :---: |
|  |  |  |  |
| Full F | $-15 \%$ | $-19 \%$ | $-15 \%$ |
| SSB | $+12 \%$ | $+15 \%$ | $+13 \%$ |
|  |  |  | $+5 \%$ |
| Total Stock Size <br> N | $+8 \%$ | $+5 \%$ | $+9 \%$ |
| Age 0 N | $+16 \%$ | $+5 \%$ | $-2 \%$ |
| Age 1 N | $+3 \%$ | $-5 \%$ | $-6 \%$ |
| Age 2 N | $-2 \%$ | $-4 \%$ | $+2 \%$ |
| Age 3 N | $+3 \%$ | $+4 \%$ | $+9 \%$ |
| Age 4 N | $+9 \%$ | $+12 \%$ | $+18 \%$ |
| Age 5 N | $+15 \%$ | $+22 \%$ | $+26 \%$ |
| Age 6 N | $+19 \%$ | $+30 \%$ | $+35 \%$ |
| Age 7+ N | $+25 \%$ | $+35 \%$ |  |

ASAP Model Building: F2018_4FLEET_BIGSWAN_CALMRIP_V2-Revision of the catch of the Recreational Landings and Discard Fleets

As a result of the first two Model Comparison workshops' consideration of alternative assessment models, the SFWG concluded that the ASAP F2018_4FLEET_BIGSWAN model was the best candidate to move forward as the primary assessment model. The next step in model development was to replace the existing ('Old’) MRIP recreational aggregate catch in weight ( mt ), catch at age in numbers, and mean weight at age ( kg ) estimates with the calibrated ('New') MRIP estimates, creating run F2018_4FLEET_BIGSWAN_CALMRIP. All other settings and fishery and survey input data remained the same.

An initial run was made to examine the need to further tune either the fishery or survey ESSs or the input CVs. Upon evaluation of the diagnostics, none of the input CVs were changed. However, the input ESSs were revised ('tuned') to the medians of the estimated ESSs of the initial 'CALMRIP' run to configure run 'CALMRIP_V2' as follows:

Commercial landings (Fleet 1): 83 to 107
Commercial discards (Fleet 2): 54 to 68
Recreational landings (Fleet 3): 66 to 53
A. Summer Flounder

Recreational discards (Fleet 4): 56 to 54
For most surveys, the input ESSs did not change or changed by only 1 or 2 digits. The largest survey ESS changes were for the NEFSC winter (56 to 73), the ChesMMAP ( 90 to 78), and the NEAMAP fall (74 to 85). The changes in the F and SSB estimates due to these changes were minimal, with the two 'CALMRIP' runs providing nearly identical estimates since 2000.

## Model Fit Diagnostics

Most of the likelihood contribution to the model fit was due to the age compositions, owing to the large number of fishery and survey catch-at-age estimates that are made. The Root Mean Square Error (RMSE) for the aggregate survey indices were all close to or inside the expected 95\% confidence for RMSE (NFT 2012b) except for the MADMF YOY index, which was still well outside the confidence interval even with the input CV increased to 1.0. The aggregate landings and discards and age composition fit diagnostics and residuals did not reveal any serious problems, although some individual residuals at age were large for the commercial and recreational discards fleets.

Some trends and/or isolated large residuals for the usual 'problematic' surveys were evident. As noted for earlier runs in the development sequence, those surveys are the DEIBYOY (DEDFW Inland Bays Young-Of-Year survey; a few large standardized residuals >2.0, and a recent pattern), the ChesMMAP (VIMS Chesapeake Bay multispecies survey; strong pattern), the NEAMAP Fall (VIMS 'inshore strata’ coastal trawl survey; strong pattern), and the URIGSO (URI two station trawl survey; strong pattern) surveys. The SFWG decided, however, to retain all available surveys in the model calibration using consensus 'appropriate' input CVs and ESSs. Overall, there were no major diagnostic problems with the 2018_4FLEET_BIGSWAN_CALMRIP_V2 model run. The model fit the fishery data well, and most of the observed survey indices were within the $95 \%$ confidence interval ( $<=2$ standardized residuals) of the model estimates.

## Comparison with other configurations

Figures A128-A129 provide a comparison of the trends in F, SSB, recruitment (model age 1 , true age 0 ), and plus group stock size (model age $8+$, true age $7+$ ) for the current (existing) two fleet with 'Old' MRIP catch model (F2018), the four fleet with BIGSWAN indices with 'Old’ MRIP catch model (F2018_4FLEET_BIGSWAN), and the four fleet with BIGSWAN indices with ‘New’ MRIP catch model (F2018_4FLEET_BIGSWAN_CALMRIP_V2). Time series trends among these model configurations are similar, but differ substantially in absolute scale. As noted earlier, most of the difference between the ' 2 fleet' and ' 4 fleet with BIGSWAN' model is due to the change from two to four fleets. Then, the $24 \%$ and $29 \%$ average increases in time series catch in numbers and weight due to the 'New' MRIP recreational fishery catch estimates result in an increase of about $40 \%$ in stock size (i.e., SSB) in the 'four fleets with BIGSWAN with 'New' MRIP' run. Going forward, the F2018_4FLEET_BIGSWAN_CALMRIP_V2 run was renamed the 'F2018_BASE' run, pending further revision by the SFWG or the SARC-66 Review Panel.

Internal model retrospective analysis

An 'internal’ retrospective analysis for the renamed F2018_BASE run was conducted to examine the stability of the model estimates as data were removed from the end of the model time series. Seven retrospective runs ('peels') were made for terminal years back to 2010. The F2018_BASE retrospective results are compared with earlier runs in the table below. Over the terminal 7 years, the annual retrospective change in fishing mortality ( F ) averaged $-3 \%$ and ranged from $-19 \%$ in 2012 to $+13 \%$ in 2015. The annual retrospective change in SSB averaged $+1 \%$ and ranged from $-7 \%$ in 2014 to $+12 \%$ 2012. The annual retrospective change in recruitment (true age 0, model age 1) averaged $+2 \%$ and ranged from $-30 \%$ in 2011 to $+30 \%$ in 2012 (table below). For the F2018_BASE run, the revision to use the 'New’ MRIP recreational fishery catch estimates generally reduced the internal retrospective pattern.
$\left.\begin{array}{|c|c|c|c|}\hline \text { Estimate } & \begin{array}{c}\text { F2018 } \\ \text { (2 fleets) }\end{array} & \begin{array}{c}\text { F2018_4FLEET_ } \\ \text { BIGSWAN }\end{array} & \begin{array}{c}\text { F2018_4FLEET_- } \\ \text { BIGSWAN_CALMRIPV2 }\end{array} \\ \text { F2018_BASE }\end{array}\right]$

## Potential Internal Estimation of Reference Points

The internal estimation of BRPs in the F2018_BASE model configuration using the Beverton-Holt (B-H; 1957) function was attempted. The model run converged successfully and provided estimates of h (steepness) $=1, \mathrm{SSB} 0=145,411 \mathrm{mt}, \mathrm{R} 0=50.3$ million, SSBMSY $=$ $26,034 \mathrm{mt}$, FMSY = 1.364, and MSY = 17,062 mt. For most Northeast U.S. finfish assessments, an estimate of FMSY (and associated BRPs) is considered to be infeasible if the value is much larger than Fmax or other FMSY proxies such as F35\% or F40\% (NEFSC 2002b, NEFSC 2008a). This is generally the case for BRPs estimated using the B-H function if the steepness parameters are estimated to be close to 1 due to the distribution of the SSB and R data pairs, as in the current F2018_BASE model results. Given this precedent, the use of an externally estimated proxy for FMSY such as the currently adopted F35\% was developed for the 2018 SAW-66 assessment.

## Likelihood Profile over assumptions for Natural Mortality (M) and Unfished Recruitment (R0)

The F2018_BASE model configuration was run over a range of input M (constant over years, constant over ages, except for the F2018_BASE model run where $M$ varies over ages from
0.26 to 0.24 with a mean of 0.25 ). The value of the objective function (or likelihood) was minimized at $\mathrm{M}=0.10$ and $\mathrm{M}=0.15$ (difference of 1 point), indicating that the model 'fit best' under that assumption. The difference in objective function value from $\mathrm{M}=0.10$ was about 6 points for $\mathrm{M}=0.20$ and about 21 points for the current average value of $\mathrm{M}=0.25$ (Figure A130). Because M profiles can vary depending on the input data and model configurations, the SFWG decided to retain the current M values due to biological considerations.

The F2018_BASE model configuration was also run over a range of fixed unexploited recruitment (R0) values and compared with the F2018_BASE model run results. The aggregate catch and index components were minimized at about $R 0=50,000$, with the index age compositions minimized at $\mathrm{R} 0=40,000$ and the catch age compositions minimized at $\mathrm{R} 0=$ 65,000 . The profile for the individual aggregate and YOY survey indices was 'flatter' than for the major aggregate components, but still with minima in the 40,000 to 65,000 range (Figures A131-A132).

## Alternatives for Calibration Index Set

Two alternative calibration index sets were considered in a limited exploration of the effects of the indices included in the model calibration. In the first (DROP_4), the four 'problematic' index series noted earlier were dropped from the model: the DEIBYOY index (multiple large residuals, pattern), the ChesMMAP index (pattern), the NEAMAP Fall index (pattern), and the URIGSO aggregate index (pattern). The second index set (NEC_ONLY) was intended to address the previously voiced concerns by SAW summer flounder Review Panels about the large number of spatially limited (i.e., state and academic agency) surveys included in the model calibration. The second calibration index set therefore included only the NEFSC winter, spring, and fall trawl survey series and the NEFSC MARMAP and ECOMON larval survey series. A comparison between the F2018_BASE, DROP_4, and NEC_ONLY runs shows that the NEC_ONLY run generally estimates lower F and higher SSB (Figure A133), with stock size N differences smallest for model age 1 (true age 0 ) and largest for model age 8 (true age 7+; Figure A134). Retrospective analyses indicate generally very similar errors for the DROP_4 run compared to the full F2018_BASE model. The NEC_ONLY configuration, however, has a different pattern of retrospective errors, as it 'flips' to a relatively 'strong' pattern with overestimation of F and underestimation of SSB and Total Stock Size N, and a different pattern of errors at age with the smallest errors at the oldest ages (see table below). These results are generally reflective of the recent differing trends in the NEFSC indices (generally stable over the last decade) versus the state and academic indices (generally decreasing over the last decade) and reinforced the SFWG decision to use the F2018_BASE run as the primary assessment model for evaluation of stock status and projections.

| Estimate | F2018_BASE | DROP_4 | NEC_ONLY |
| :---: | :---: | :---: | :---: |
|  |  |  |  |
| Full F | $-3 \%$ | $-1 \%$ | $+64 \%$ |
| SSB | $+1 \%$ | $-3 \%$ | $-39 \%$ |
| Total Stock Size N | $-2 \%$ |  |  |
| Age 0 N | $+2 \%$ | $-6 \%$ | $-41 \%$ |
| Age 1 N | $-9 \%$ | $+2 \%$ | $-40 \%$ |
| Age 2 N | $-13 \%$ | $-14 \%$ | $-53 \%$ |
| Age 3 N | $-7 \%$ | $-18 \%$ | $-48 \%$ |
| Age 4 N | $-1 \%$ | $-9 \%$ | $-41 \%$ |
| Age 5 N | $+5 \%$ | $-2 \%$ | $-35 \%$ |
| Age 6 N | $+11 \%$ | $+5 \%$ | $-31 \%$ |
| Age 7+ N | $+20 \%$ | $+11 \%$ | $-27 \%$ |

## Fishery Selection Sensitivity Runs

A first fishery selection sensitivity run of the F2018_BASE model was made that reduced the number of selectivity time blocks for all four fleets from three to two, by combining the last two blocks (1995-2007, 2008-2017) into one (1995-2017). In this SELEX_2BLK run, the changes from three to two selectivity blocks reduced the 'doming' in the landed fleets for ages 5 and older (true ages 4 and older) after 1995, from about 0.70 to $0.8-0.9$. However, other associated changes in the pattern back in time resulted in a different trend in average F , so that average F (fully recruited at model age $5=$ true age 4 ) was estimated to be higher during 19952006 than in F2018_BASE, and lower since 2007. This F trend translated to higher SSB and stock size at older ages in the SELEX_2BLK run since 2007 (Figures A135-A136). The SFWG decided to keep the three selectivity block model because the changes from block 2 to block 3 make sense given the changes in the management measures over time and the selectivities at age are estimated with good precision (CV < 30\%).

A second sensitivity run of the F2018_BASE model was made that forced flat-topped selectivity ( $\mathrm{S}=1$ ) at model ages 5 and older (true ages 4 and older) for the two landings fleets in the most recent (2008-2017) time blocks. The forced flat-topped selection for the landings fleets in this SELEX_FLATLAND run produced an F trend and magnitude comparable to F2018_BASE, slightly lower SSB since 2008, and lower stock sizes at the oldest ages since 2007 (Figures A135-A136). The SFWG decided not to force flat topped selectivity for the landed fleets because the estimated selectivities in the F2018_BASE run are not extreme, make sense given the changes in the fisheries over time, and are estimated with good precision ( $\mathrm{CV}<0.30$ ).

## State/Academic 'Hierarchical Index’ Sensitivity Run

As noted in TOR2, the summer flounder assessment includes multiple state and academic fishery independent survey indices of abundance. These indices have relatively restricted temporal and spatial scope compared to the NEFSC indices, but are believed to provide useful information on population trends. A Bayesian hierarchical approach (Conn 2010) was applied to develop aggregate state/academic research survey indices for use in summer flounder population models. This approach is a technique to combine numerous noisy indices of abundance into a
single time series. The method works by assuming that each CPUE index is attempting to sample relative abundance but is subject to both sampling and process errors. Each index is represented as a CPUE mean from the fishery independent trawl surveys in the input data set. Different levels of aggregation and combinations of the indices were considered, with the SFWG recommending aggregation of the young-of-the-year (YOY) indices into a single state/academic 'YOY' index and aggregation of the adult indices into a single state/academic 'adult' index.

An 'aggregate Young-of-the-Year' (YOY) index was constructed from the available stand-alone YOY indices: MADMF seine, DEDFW estuarine, DEDFW inland bays, MDDNR, VIMS juvenile, and NCDMF juvenile. An 'aggregate adult' index included the MADMF spring and fall, RIDMF fall and monthly, CT DEEP spring and fall, NY Peconic Bay, NJ Ocean, DE 30 foot, VIMS ChesMMAP, and NEAMAP spring and fall trawl surveys. The MARMAP larval SSB index, ECOMON larval SSB index, and URIGSO trawl surveys index were not included in the aggregate adult indices because they did not include accompanying age compositions. To develop an age composition for the 'aggregate adult' index, the proportions at age of the individual survey age compositions were averaged by using the inverse sigma estimate of each contributing index from the hierarchical approach to compute an overall weighted average proportion at age, which was then applied to the annual aggregate indices to produce 'aggregate adult' indices at age. These aggregated 'hierarchical' indices were used in a HIER_V2 sensitivity run for comparison to the F2018_BASE_V2 run of the assessment model. In the HIER_V2 model, the stand-alone YOY indices were replaced by the 'aggregate YOY' index, and the contributing, full age composition indices were replaced by the 'aggregate adult' indices and accompanying age compositions. The NEFSC ALB winter, spring and fall, NEFSC BIG spring and fall, MARMAP, ECOMON, and URIGSO indices remained as calibration indices in the sensitivity (McNamee 2018 MS).

In this HIER_V2 run, there is significantly more 'doming' in the fishing fleets selectivity patterns for ages 5 and older (true ages 4 and older) after 1995 when compared to the F0218_BASE_V2 run (note that the hierarchical index work was completed after the September 2018 SFWG meeting in which the final model F2018_BASE_V2 was configured and selected as final, was based on that final model, and so is compared to that final model described in the next section). The aggregate (across all fleets) selectivities at ages 5-7+ are $0.88,0.68$, and 0.28 in the HIER_V2 run, and 0.91, 0.88, and 0.65 in the F2018_BASE_V2 run. Combined with apical (model age 5, true age 4) F estimates that are about 20-30\% lower than in the F2018_BASE_V2 run, the HIER_V2 model therefore provides higher SSB and stock size estimates (Figures A137A138). The HIER_V2 run does have larger retrospective errors, however, at $+12 \%$ for F (overestimation of F) and $-13 \%$ for SSB (underestimation of SSB), and $-8 \%$ for recruitment at age 0 . In addition, the SFWG noted some concern over the residual patterns for the survey age compositions that may relate to the manner in which the 'aggregate adult' age composition was constructed, an aspect of the hierarchical 'aggregate index' approach that the SFWG felt needed more work.

## 2018 FINAL MODEL: ASAP F2018_BASE_V2

The SFWG made a few additional decisions and modifications to F2018_BASE in the final meeting held in September 2018, resulting in a final model run renamed F2018_BASE_V2. After further discussion about the suite of survey indices to be included in the model, the SFWG reaffirmed its' decision to include all the available indices, including the 'DROP_4' indices,
because a) it was difficult to arrive at a set of 'non-arbitrary' criteria for inclusion/exclusion, b) with the addition of the 'New' MRIP recreational catch data, the size and patterns of some of the residuals for the 'DROP_4' indices improved, while those of some indices not originally considered as candidates for exclusion deteriorated, c) the model results were relatively insensitive to inclusion of the 'DROP_4' indices due to input CV and ESS weight effects, and d) including all the available indices most fully expresses the overall uncertainty of the model and assessment results.

The SFWG noted some minor but persistent patterning/blocking in the commercial and recreational landings age compositions in most of the years of the time series when landings at the youngest ages were very small (i.e., since about 1990). These residual patterns are due to the small magnitude of those estimated landings at model ages 1 and 2 (true ages 0 and 1) and model estimates of stock size at age that are consistently larger than those 'observed' landings. The F2018_BASE_V2 model estimated the landings selectivity for both fisheries at 1-2\% since 1995, so these residual patterns are not considered to be problematic. Figures A139-A142 show the estimated selectivity patterns for the four fleets in the F2018_BASE_V2 three selectivity time block model.

Finally, the SFWG made minor changes in the survey selectivity settings (shifting the age of assumed full selection by one age class) for the NEAMAP spring and NEFSC BIGSWAN spring indices. These two changes improved the age composition residual patterns for those indices. Run F2018_BASE_V2 provided estimates that had very minor differences from the previous run, and so the alternative run configuration comparisons and profiles were not repeated. However, the final model diagnostics, final model estimates, internal retrospective, and MCMC analyses were updated.

## Model Fit Diagnostics

Most of the likelihood contribution to the model fit was due to the age compositions, owing to the large number of fishery and survey catch-at-age estimates that are made (Figure A143). The Root Mean Square Error (RMSE) for the aggregate survey indices were all close to or inside the expected 95\% confidence for RMSE (NFT 2012b) except for the MADMF YOY index, which was still well outside the confidence interval even with the input CV increased to 1.0 (Figure A144). The aggregate landings and discards and age composition fit diagnostics and residuals did not reveal any serious problems, although some individual residuals at age were large for the commercial and recreational discards fleets, and as noted earlier there is some patterning/blocking for the youngest ages in the landings fleets (Figures A145-A152). Figures A149 and A151 show the previously noted minor but persistent patterning in the commercial and recreational landings age compositions in most of the years of the time series when landings at the youngest ages were very small (i.e., since about 1990). These residual patterns are due to the small magnitude of those estimated landings at model ages 1 and 2 (true ages 0 and 1) and model estimates of stock size at age that are consistently larger than those 'observed' landings. The F2018_BASE_V2 model estimated the landings selectivity for both fisheries at 1-2\% since 1995, so these residual patterns are not considered to be problematic.

Some trends and/or isolated large residuals for the DROP_4 'problematic' surveys were again evident. As noted for earlier runs in the development sequence, those surveys are the DEIBYOY (DEDFW Inland Bays Young-Of-Year survey; a few large standardized residuals >2.0, and a recent pattern), the ChesMMAP (VIMS Chesapeake Bay multispecies survey; strong
pattern), the NEAMAP Fall (VIMS ‘inshore strata’ coastal trawl survey; strong pattern), and the URIGSO (URI 2 station trawl survey; strong pattern) surveys. As noted earlier, however, during the course of model development other patterns for other indices also emerged, in particular the appearance of more than one or two large annual residuals (e.g., for the MADMF spring, the RIDFW fall, and CTDEEP spring, the MADMF YOY). The SFWG decided, therefore, to retain all available surveys in the model calibration using consensus 'appropriate' input CVs and ESSs.

Overall, there were no major diagnostic problems with the F2018_BASE_V2 model run. The model fit the fishery data well, and most of the observed survey indices were within the $95 \%$ confidence interval ( $<=2$ standardized residuals) of the model estimates (Figures A153-A195).

## Internal model retrospective analysis

An 'internal' retrospective analysis for the F2018_BASE_V2 run was conducted to examine the stability of the model estimates as data were removed from the end of the model time series. Seven retrospective runs ('peels’) were made for terminal years back to 2010. Over the terminal 7 years, the annual retrospective change in fishing mortality ( F ) averaged -4\% (underestimated by 4\%) and ranged from $-21 \%$ in 2012 to $+12 \%$ in 2015 (Figure A196). The annual retrospective change in SSB averaged $+2 \%$ (overestimated by 2\%) and ranged from $-6 \%$ in 2014 to $+14 \% 2012$ (Figure A197). The annual retrospective change in recruitment (true age 0 , model age 1) averaged $+2 \%$ (overestimated by $2 \%$ ) and ranged from $-29 \%$ in 2011 to $+31 \%$ in 2012 (Figure A198). For the F2018_BASE_V2 run, the revision to use the calibrated ('New’) MRIP estimates of recreational catch generally reduced the internal retrospective pattern compared to models using the 'Old' MRIP estimates.

## Model estimates of stock size and fishing mortality

The F2018_BASE_V2 estimates of instantaneous fishing mortality (F; fully recruited at model age 5, true age 4) and Spawning Stock Biomass (SSB) in 2017 were 0.334 and 44,552 mt (Table A87). The retrospectively adjusted estimates were 0.348 and $43,678 \mathrm{mt}$. An MCMC run was made to evaluate the precision of the estimates and help judge the magnitude of the retrospective pattern. One million MCMC iterations were made, of which one thousand were saved, that provided median $F$ in 2017 of 0.324 , with a $90 \%$ confidence interval (CI) from 0.276 to 0.380 (Figure A199). The median SSB in 2017 was estimated to be $44,647 \mathrm{mt}$, with a $90 \%$ CI from 39,195 mt to 50,935 mt (Figure A200). Given recent standard procedures for Northeast stock assessments that use complex age-structured population models (e.g., NEFSC [2013] for summer flounder and NEFSC [2017] for New England groundfish), because the retrospectively adjusted terminal year estimates fall within the $90 \%$ CI for both $F$ and SSB, the F2018_BASE_V2 model run for summer flounder would be considered to have a minor retrospective pattern, with no adjustment to the terminal year estimates needed to evaluate stock status or conduct projections. Estimates of F at age and stock numbers at age from the F2018_BASE_V2 model run are presented in Tables A88-A89.

## Historical Retrospective Analyses

The F, SSB, and recruitment estimates from the 2008 SAW 47 benchmark assessment, the 2009-2012 assessment updates, 2013 SAW 57 benchmark assessment, the 2015-2016
assessment updates, the existing (‘Old’) model updated through 2017 with ‘Old’ MRIP (F2018_OLD_MODEL) , and the final F2018_BASE_V2 model with 'New' MRIP for the 2018 SAW-66 assessment are compared in Figures A201-A202. The ASAP model has been used in the assessment during the 2008-2016 period, but due to changes in fishery selectivity estimation, 'fully-recruited' F is reported for ages 3-7+ in the 2008-2012 assessments, but only for 'peak' model age 5 (true age 4; $\mathrm{S}=1$ ) in the 2013 and later assessments.

A longer term retrospective look over all assessments dating back to 1990 is provided in Figure A203. It should be noted that the ADAPT Virtual Population Analysis (VPA) model was used for the 1990-2007 assessments, and fully recruited F was reported for age 2-7+. Also, the assumed value for natural mortality (M) changed from 0.2 for all ages in the 1990-2007 assessments to an average value of 0.25 in the 2008-2018 assessments. Despite these changes in model estimation procedures, configurations, and assumptions, these 'historical' retrospectives indicate that general trends of fishing mortality and stock biomass have been consistent since the 1990s assessments. The use of the new calibrated estimates of recreational landings and discards in the current assessment increased the 1982-2017 total catch by an average of almost $30 \%$. While the magnitude of fishing mortality was not strongly affected, the increased catch has resulted in increased estimates of stock size compared to the historical assessments.

## Other Supportive Model Comparisons

Several other models were examined and considered as part of the SFWG model building process, through the two Model Comparison workshops and the September 2018 Data/Model meeting. While not the final model choice of the SFWG, these other modeling approaches are briefly presented to support the SFWG final model choice and provide additional sensitivities. Because these other models are under development, they are not a substitute for the final model, nor should they be used as a basis for developing management advice.

Figures A204-A205 compare the model outputs (SSB and Full F) from these 'other' models to the final model run (ASAP_BASE_V2). After exploring these models, the SFWG concluded that gains from the additional sex-specific information were not shown and did not warrant selection of less developed models that required additional parameters and assumptions. As shown in Figures A204-A205, these models show similar trends and capture major year class signals, despite being configured slightly differently. The following models were developed:
A) ASAP_BySex (Terceiro 2017 MS)

Independent sex-specific ASAP models for males and females were developed. The 2008 SARC 47 natural mortality vector at age for the sexes was used in this model. These models have all the same data as the final assessment model, except that the mean weights at age in the fishery landings and discards are derived from the NEFSC spring and fall survey data (to use the available lengths and weights by sex), rather than from fishery data as in the final assessment model. All the 'model settings' (lambdas, CVs, ESSs) were left the same in all runs - no individual run 'tuning' was performed. The diagnostics (residuals, RMSEs, retrospective analyses) looked reasonable. The spawning stock biomass and mean F from the male and female models were summed/averaged for comparison.
B) Stock Synthesis implementation of sex-structured virtual population analysis (Maunder 2018 MSa)
A Stock Synthesis model was developed that mimicked a sex-structured Virtual Population Analysis. The features included flexible initial numbers at age, time varying sex and age-specific selectivity, freely estimated recruitment, and the use of weight-at-age data. The model would need to go through a systematic model building and diagnostic approach before further consideration. It was constructed to be like the current ASAP model; however, there are differences in this implementation from the final ASAP_BASE_V2 model. For example, only the NEFSC surveys were used.
C) Sex-Age-Length (SAL) structured model (Sullivan 2018 MS)

This model was constructed in Template Model Builder (TMB) to address sex specific differences in growth and mortality that can result in differences in size specific selectivity by fishery. Preliminary analyses have been conducted using simulated data. The model is being applied to the actual sex-age-length based data derived from currently available data sources and configured using the NEFSC survey data and four fleet configuration. While outputs are not yet deemed reliable (not shown in Figures A204-A205), this model framework could be a candidate for future assessments.
D) State-space, sex-specific, age-structured assessment model (Miller and Terceiro 2018a, b MS)
The general state-space model was configured in various ways over the series of SFWG meetings. This approach uses the population models described by Miller et al. (2016) and Miller and Hyun (2018) for each sex, but with certain parameters shared by the two sexes. In Miller and Terceiro (2018b MS), revised recreational catch and discard data were used, but unlike the final ASAP_BASE_V2, only the NEFSC surveys were used for relative abundance indices, as was also done for all the non-final models. The differences in numbers at age for males and females were informed by observations of the proportion at age in the NEFSC surveys. The likelihood for these data was a generalization of the zero-or-one inflated beta distribution described by Ospina and Ferrari (2012) to deal with zeros and ones along with the proportions that would otherwise be modeled with a beta distribution.

Miller and Terceiro (2018a, b MS) focused on estimation of three models that assumed different age- and size-based selectivity and differences in selectivity by sex. Size effects on selectivity were modeled using empirical estimates of size at age. Ultimately there was no statistical evidence (as measured by AIC) found for differences in selectivity at age by sex, and size-based selectivity did not outperform age-based selectivity. Figures A204-A205 present the simplest and best model fit (based on AIC) without sex effects on selectivity. However, there were differences in recruitment and the assumed natural mortality differed for each sex. Therefore, per-recruit-based biological reference points that accounted for sex were also explored (Miller 2018 MS).

TOR A5. State the existing stock status definitions for "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; point estimates or proxies for BMSY, BTHRESHOLD, FMSY and MSY) and provide estimates of their uncertainty. If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs.

## BIOLOGICAL REFERENCE POINTS (BRPs)

## Background

The calculation of biological reference points for summer flounder based on yield per recruit analysis using the Thompson and Bell (1934) model was first detailed in the 1990 SAW 11 assessment (NEFC 1990). The 1990 analysis estimated that Fmax $=0.230$. In the 1997 SAW 25 assessment (NEFSC 1997) an updated yield per recruit analysis reflecting the fishery selection pattern and mean weights at age for 1995-1996 estimated that Fmax $=0.240$. The Overfishing Definition Review Panel (Applegate et al. 1998) recommended that the MAFMC base MSY proxy reference points on yield per recruit analysis and this recommendation was adopted in formulating the FMP Amendment 12 Overfishing Definition (MAFMC 1999). These reference points were based on the 1999 assessment (Terceiro 1999) and followed what would later be described as the 'non-parametric approach’ (i.e., biomass reference points calculated as the product of biomass per recruit and a reference period recruitment level; NEFSC 2002b). The analysis in the Terceiro (1999) assessment, reflecting fishery selection and mean weights at age for 1997-1998, indicated that Fthreshold $=$ Fmax $=0.263$, yield per recruit $(\mathrm{Y} / \mathrm{R})$ at Fmax was $0.552 \mathrm{~kg} /$ recruit, and Jan 1 Total Stock Biomass per recruit (TSB/R) at Fmax was 2.813 $\mathrm{kg} /$ recruit. The median number of summer flounder recruits estimated from the 1999 assessment for 1982-1998 was 37.8 million age-0 fish. Based on this median recruitment level, maximum sustainable yield (Ymax as a proxy for MSY) was estimated to be $20,897 \mathrm{mt}$ ( 46.070 million lb) at a Total Stock Biomass (TSBmax as a proxy for BMSY) of 106,444 mt (234.669 million lb). The biomass threshold, one-half TSBmax as a proxy for one-half BMSY, was therefore estimated to be 53,222 mt (117.334 million lb). The Terceiro (1999) reference points were retained in the 2000 SAW 31 assessment (NEFSC 2000) because of the stability of the input data and resulting biological reference point estimates.

The MAFMC SSC conducted a peer review of the summer flounder Overfishing Definition in concert with the 2001 assessment (MAFMC 2001a, b). The 2001 SSC reviewed six analyses estimating biological reference points for summer flounder that were conducted by members of the Summer Flounder Biological Reference Point Working Group. The 2001 SSC decided that although the new analyses conducted by the Working Group had resulted in a wide range of estimates, they did not provide a reliable alternative set of reference points for summer flounder. The 2001 SSC therefore recommended that Fthreshold remain at the Terceiro (1999) estimate of Fmax $=0.263$ because a better estimate had not been established by any of the new analyses. The 2001 SSC also reviewed the biomass target (BMSY) and threshold (one-half BMSY) components of the Overfishing Definition and concluded that the new analyses did not justify an alternative estimate of the BMSY proxy. The 2001 SSC endorsed the recommendations of the 2000 SAW 31 which stated that 'The use of Fmax as a proxy for FMSY should be reconsidered as more information on the dynamics of growth in relation to biomass
and the shape of the stock recruitment function become available’ (NEFSC 2000). The 2001 SSC agreed that additional years of stock and recruitment data should be collected and encouraged further model development, including model evaluation through simulation studies. They also encouraged the evaluation of alternative proxies for biological reference points that might be more appropriate for an early maturing species like summer flounder and the development and evaluation of management strategies for fisheries where BMSY is unknown. The 2001 SSC indicated that as the stock size increases, population dynamic processes that could reflect density dependent mechanisms should be more closely monitored and corresponding analyses should be expanded, i.e., rates of size and age, maturity, fecundity, and egg viability should be closely monitored as potential indicators of compensation at higher stock sizes. Finally, the 2001 SSC recommended that potential environmental influences on recruitment, including oceanographic changes and predation mortality, should be reevaluated as additional recruitment data become available. As a result of the 2001 SSC peer review (MAFMC 2001a) the Terceiro (1999) reference points were retained in the 2001 stock assessment (MAFMC 2001b). In the review of the 2002 stock assessment (NEFSC 2002a), SAW 35 concluded that revision of the reference points was not warranted at that time due to the continuing stability of the input data and resulting reference point estimates. The Terceiro (1999) reference points were subsequently retained in the 2003 (Terceiro 2003a) assessment.

The biological reference points for summer flounder were next peer-reviewed by the 2005 SAW 41, using fishery and survey data through 2004 (NEFSC 2005). The SAW 41 Panel noted that the Beverton-Holt (Beverton and Holt, 1957; Mace and Doonan 1988; BH) model fit the observed stock-recruitment data well, and provided reference points comparable to those derived from a non-parametric (yield and biomass per recruit) approach. The SAW 41 Panel noted, however, that the quantity of observed stock-recruitment data was limited (22 years), and the data during the early part of the time series, when the SSB was at the lowest observed levels, indicated a level of recruitment near the estimated Rmax, and exerted a high degree of leverage on the estimation of the model parameters. This leverage resulted in a high value (0.984) for the calculated steepness (h) of the BH curve, outside of the $\pm$ one standard error interval of the estimate for Pleuronectid flatfish ( $0.8 \pm 0.1$ ) indicated by Myers et al. (1999). The BH model results suggested that summer flounder SSB could fall to very low levels ( $<2,000 \mathrm{mt}$ ) and still produce recruitment near that produced at SSBMSY. The SAW 41 Panel concluded a) that this result might not be reasonable for the long term, given the recent stock-recruitment history of the stock (i.e., production of a very poor year class in 1988), b) the BH model estimated parameters might prove to be sensitive to subsequent additional years of S-R data, especially if they accumulated at higher levels of SSB and recruitment in the near term, and c) the BH model fit might also be sensitive to the magnitude of recently estimated spawning stock and recruitment, given the recent retrospective pattern of overestimation of stock size evident in the assessment. Given these concerns, the SAW 41 Panel advised that the BH model estimates were not suitable for use as biological reference points for summer flounder, and recommended continued use of reference points developed using the non-parametric model approach. FMP biological reference points from the 2005 assessment were FMSY $=$ Fmax $=0.276$, MSY $=$ Ymax $=19,072 \mathrm{mt}$ ( 42.047 million lb ), BMSY $=$ TSBmax $=92,645 \mathrm{mt}(204.247$ million lb), and biomass threshold of $0.5 *$ TSBmax $=46,323 \mathrm{mt}$ (102.125 million lb; NEFSC 2005).

The biological reference points for summer flounder were peer-reviewed again in 2006 by the National Marine Fisheries Service (NMFS) Office of Science and Technology (S\&T). The 2006 S\&T Peer Review recommended using SSB, rather than TSB as in previous assessments, as
the metric for the biomass reference point proxy. The product of the mean recruitment (37.0 million fish) and Y/R at Fmax was $21,444 \mathrm{mt}=47.276$ million lb (as the proxy for MSY); the product of the mean recruitment and $\mathrm{SSB} / \mathrm{R}$ at Fmax was $89,411 \mathrm{mt}=197.118$ million lb (as the proxy for BMSY; Terceiro 2006a, b). The 2006 S\&T Peer Review Panel (Methot 2006) recommended adoption of these biological reference points from the non-parametric approach for summer flounder, advising:
"The low level of recruitment observed in 2005 is essentially the same as the low 1988 recruitment, so it is within the range of recruitment fluctuation used in calculating the expected time to rebuild this stock. The Panel finds that the most representative approach to calculating BRPs and rebuilding rates would be to use the entire set of recruitments from 1982-2005. The average, not median, of these recruitments should be used for calculation of biological reference points because much of the stock's accumulated biomass comes from the larger recruitments. Random draws from this set of recruitments would provide a probability distribution of rebuilding rates that is consistent with the occasional occurrence of small recruitments (1988 and 2005) and large recruitments (1982-1987). There is no documented and obvious reason why recruitments were higher during 1982-1987. If such recruitment levels become more common as the stock rebuilds, then the stock may rebuild to an even higher level than is currently targeted. If such recruitment levels do not occur during the next few years of the rebuilding, then the rebuilding target may be not be achieved by the target time to rebuild. More precise forecasts than this are not feasible."

The two biological reference point estimation approaches previously used in the 2005 SAW 41 (NEFSC 2005) and 2006 S\&T Peer Review (Terceiro 2006b) assessments were again applied in the 2008 SAW 47 benchmark assessment work (NEFSC 2008). Objective application of either approach is often compromised by lack of sufficient observation of stock and recruitment over a range of biomass to provide suitable contrast. Thus, it is often necessary to extrapolate beyond the range of observation and to infer the shape of the stock-recruit relationship from limited and variable observations (NEFSC 2002b). The 2001 MAFMC SSC review of summer flounder reference points also noted this concern (MAFMC 2001a).

The non-parametric approach was to evaluate various statistical moments (mean, variance, percentiles) of the observed series of recruitment data and apply the estimated spawning stock biomass and yield per recruit associated with common F reference points to derive the implied spawning stock biomass and equilibrium total yield (landings plus discards). The biomass and yield per recruit models were fit using the NOAA Fisheries Toolbox (NFT) YPR software (NFT 2013b). The full time series of recruitment during 1982-2007 as estimated in the 2008 SAW47 assessment was used in the yield and spawning stock biomass calculations at fishing mortality reference points, as per the 2006 S\&T Peer Review Panel recommendation. The non-parametric approach assumes that compensatory mechanisms such as impaired growth, maturity, or recruit survival are negligible over the range of biomass considered (NEFSC 2002b). Once the Fmax reference point (i.e., the Fmax proxy for FMSY) was determined, a long-term (100 year) stochastic projection of stock sizes and catches was done to provide better consistency between the estimated medians of the BRP calculations and shorter-term (e.g., 1-5 year) projections (Legault 2008 MS).

The parametric approach used fitted parametric stock-recruitment models along with yield and spawning biomass per recruit information to calculate MSY-based reference points following the procedure of Sissenwine and Shepherd (1987). Stock-recruitment models were fit using the NFT SRFIT version 6 software (NFT 2008). Since a wide range of models (Beverton-

Holt [BH] and Ricker [RK] models, incorporating autoregressive error, and Bayesian priors for various parameters) had been tested in the 2005 SAW 41 work, the 2008 SAW47 parametric model exercise was limited to the simple Beverton-Holt and Ricker models (Beverton and Holt 1957, Mace and Doonan 1988, Ricker 1954, 1975).

The reference points estimated in the 2008 SAW 47 assessment using the parametric approach were suspect because the Beverton-Holt function steepness (h) parameter was always very near 1. Therefore Fmax, F40\%, and F35\% (and their corresponding biomass reference points) from the non-parametric approach were considered as candidate proxies for FMSY and BMSY. Fmax had been used in previous assessments as the proxy for FMSY. The estimate of Fmax using mean $\mathrm{M}=0.25$ and updated fishery selectivity and mean weights at age was relatively high ( 0.558 ) and the YPR to F relationship did not indicate a well-defined peak. As a result, little gain in YPR ( $<5 \%$ ) was realized at fishing mortality rates higher than F35\% $=0.310$. However, the corresponding decline in SSBR between F35\% = $0.310(\sim 1.48 \mathrm{~kg} / \mathrm{r})$ and Fmax $=$ $0.558(\sim 0.93 \mathrm{~kg} / \mathrm{r})$ was about $37 \%$. The 2008 SAW47 concluded that $\mathrm{F} 40 \%=0.254$ and $\mathrm{F} 35 \%=$ 0.310 were viable candidate proxies that provided sufficient YPR (F40\% YPR $=92 \%$ of Fmax YPR; F35\% YPR = 97\% of Fmax YPR) to allow for productive fisheries while also providing for substantial SSBR (F40\% SSBR = 176\% of Fmax SSBR; F35\% SSBR = 155\% of Fmax SSBR) to buffer against short-term declines in recruitment. Recommended proxies for FMSY and SSBMSY were $\mathrm{F} 35 \%=0.310$ and the associated MSY $(13,122 \mathrm{mt}=28.929$ million lb) and SSBMSY ( $60,074 \mathrm{mt}=132.440$ million lb) estimates from long-term stochastic projections. These 2008 SAW47 BRPs based on F35\% were subsequently adopted by the NMFS and MAFMC in the 2009 fishery regulation specification process, and were retained in the 20092012 updated assessments to evaluate stock status (Terceiro 2009, 2010, 2011, 2012).

## Old (Existing) 2013 SAW 57 Reference Points

In developing recommendations for biological reference points, the 2013 SAW 57 SFWG reviewed previous work on the subject. Shertzer and Conn (2012) conducted analyses that tested relationships between steepness and two life-history parameters linked to longevity ( M and maturity) and found that in neither case was steepness significantly related to the life-history parameter. In Maunder (2012) and Maunder (2013 MS), steepness parameters were examined for summer flounder using a Stock Synthesis model and information from the 2008 SAW 47 assessment, and it was proposed that a conservative 0.8 value of steepness value suggests a maximum SPRMSY = 30\% target proxy and accordingly a lower SPRMSY/SPR0 threshold proxy than the existing F35\% proxy would be appropriate. Rothschild at el. (2012) conducted a simulation study of summer flounder biological reference points and also concluded that a SPR proxy less than the existing summer flounder reference points better corresponded to MSY and was appropriate. Mangel et al. (2013) examined fixing steepness and life history parameters for both production and age-structured models and concluded that priors could be used to estimate the S-R function if needed, but that if steepness was 1 , the use of other proxies was appropriate. The 2013 SFWG used the NFT programs ASAP (NFT 2013a), YPR (NFT 2013b), and AGEPRO (NFT 2013c) to estimate parametric and non-parametric reference points for summer flounder.

The parametric reference points estimated internally in ASAP for the 2013 SAW 57 final model run were suspect because the Beverton-Holt function steepness parameter was very near 1 , and the FMSY was estimated to be 3.0, constrained at the estimation boundary. Therefore,
non-parametric Spawner per Recruit (SPR) reference points such as F40\%, F35\%, and F30\% (and their corresponding biomass reference points) were considered as candidate proxies for FMSY and SSBMSY. Fmax had been used in assessments prior to 2008 as the proxy for FMSY, with the most recent 2008 SAW 47 assessment using F35\% as the proxy. The estimate of Fmax using mean $M=0.25$ and updated fishery selectivity and mean weights at age was relatively high ( 0.480 ) and the Yield per Recruit (YPR) to F relationship did not indicate a well-defined peak. The 2013 SAW 57 discussed the merits of $\mathrm{F} 30 \%=0.378$ and $\mathrm{F} 35 \%=0.309$ as the fishing mortality reference point proxy. F30\% provided an increase of about 2\% in YPR over F35\%, but a corresponding decline in Spawning Stock Biomass per Recruit (SSBR) of 14\%. The 2013 SAW 57 SFWG recommended proxies for FMSY and SSBMSY of F35\% = 0.309 (CV = $15 \%$ ) and associated estimates from long-term stochastic projections of MSY $=12,945 \mathrm{mt}$ ( 28.539 million $\mathrm{lb} ; \mathrm{CV}=13 \%$ ) and $\mathrm{SSBMSY}=62,394 \mathrm{mt}$ ( 137.555 million $\mathrm{lb} ; \mathrm{CV}=13 \%$ ). The biomass threshold of one-half SSBMSY was estimated to be $31,197 \mathrm{mt}$ ( 68.8 million lb; CV = 13\%).

## New (Updated) 2018 SAW-66 Reference Points

## Fishing mortality reference point

The parametric reference points estimated internally in ASAP for the 2018 SAW-66 final ASAP model run F2018_BASE_V2 were suspect because the Beverton-Holt function steepness parameter was very near 1 and the FMSY was estimated to be 1.3. Therefore, as in the previous two benchmark assessments, the non-parametric reference point of F35\% and the corresponding biomass and yield reference points were used as a proxies for FMSY, SSBMSY, and MSY. Table A90 provides the input data and assumptions for the SSBR and YPR model used to compute the non-parametric reference points based on the F2018_BASE_V2 model run.

The 2018 SAW-66 SFWG recommended a proxy for the fishing mortality threshold FMSY of $\mathrm{F} 35 \%=0.448(\mathrm{CV}=15 \%)$. The SFWG noted that that the estimate of F35\% ( 0.448 ) is $45 \%$ higher than the 2013 SAW 57 value ( 0.309 ; Table A91). This is due mostly to reductions in mean weights at the older ages (ages 6-7+) from the 2010-2012 averages used in the 2013 SAW 57 calculations (a 3 year average was the accepted period then) to the 2013-2017 averages used in the current calculations (a 5 year average has become the standard period in most NEFSC groundfish assessments; NEFSC 2017) . For example, the SSB mean weights at ages 6 and 7+ were 2.227 kg and 3.561 kg in the 2013 SAW 57 calculations, but 1.758 kg and 1.964 kg in the current calculations, decreases of $21 \%$ and $45 \%$ (Figure A206 top panel). The current fishery selectivity proportions are now slightly more 'dome-shaped' for ages 5 and older than the 2013 proportions, while the proportions mature are very similar (Figure A206 middle and bottom panels).

In previous summer flounder benchmark assessments (NEFSC 2008a, 2013) for older aged fish with limited, highly variable, or missing samples, Gompertz functions based on younger ages were used to estimate mean weights for the older ages in the BRP calculations. Specifically, the mean weight at age for the plus group (ages 7+) was estimated by using a weighted average of mean weights for ages 7-15 (observed catch weights for ages 7-10; Gompertz calculated weights for ages $11-15$ as estimated from observed ages $0-10$ ) based on the relative proportions at age given a total mortality rate of 0.55 (mean $\mathrm{M}=0.25+\mathrm{F}=0.30$; a value then generally consistent with the F35\% proxies for FMSY). In the current assessment, there is
sufficient, consistent data for ages 5 and older from the NEFSC fisheries sample data since 2010 (e.g., Tables A32-A33, Figures A4-A5) to use the mean weights directly for older ages and to then calculate the plus group mean weight. Although the fishery data are not sampled by sex, the NEFSC survey sample data by sex indicate that the decrease in mean weights at older ages in survey samples is due in part to the increasing contribution that smaller male fish have to the mean weights of those ages since 2010, and in part to the decreases in in mean length exhibited by both sexes (and by extension mean weight; e.g., Figures A63-A64, A74-A75, A78-A79).

Sensitivity calculations of the F35\% value were made to judge the relative impact of the changes in fishery mean weights and fishery selectivities at ages 5-7+. The table below shows that most of the difference in the value of F35\% is due to the change in mean weights at age. Changing only the fishery selectivity for ages 5-7+ (SELEX column) from the 2018 values to the 2013 values reduces F35\% from 0.448 to 0.437 , while changing only the age 5-7+ mean weights (fishery and SSB; XW) reduces F35\% from 0.448 to 0.334 . Changing both sets of age 5-7+ inputs (XW+SELEX) reduces the F35\% to 0.322, close to the 2013 SAW 57 estimate of 0.309 .

| Sensitivity Runs | If age $5-7+$ XW and/or Selex like 2013 SAW57 |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| SAW-66 | SELEX | XW | XW+SELEX | SAW57 |
| 0.448 | 0.437 | 0.334 | 0.322 | 0.309 |

## Biomass and Yield reference points

The SFWG developed two sets of biomass (SSBMSY) and yield (MSY) reference points, using long-term (100 year) projections, that correspond to the FMSY proxy $=\mathrm{F} 35 \%=0.448$. Termed 'recommended' and 'alternative,' they differ in the magnitude of recruitment assumed for the future. The SFWG discussion justifying the development of the alternative BRPs considered whether the use of recent recruitment (the 'alternative') was more 'dynamic' and potentially better represented environmental/climatic conditions in the near future than the 'recommended', which as in previous assessments used the full time series of recruitment (Maunder 2018 MSb).

The SFWG considered the 'recommended' BRPs and associated OFL projections (TOR 7) to be the 'most realistic,' and the recommended status evaluation (TOR 6) is therefore based on those BRPs. The recommended BRPs assume that the magnitude of recruitment estimated for the full time series of the assessment (scenario 'R36': 1982-2017, with a median of 51 million age 0 fish) will persist into the future. The recommended estimates are MSY $=15,973 \mathrm{mt}(35.214$ million lb; CV = 15\%) and SSBMSY = 57,159 mt (126.014 million lb; CV = 15\%; Table A91). The recommended biomass threshold of one-half SSBMSY was estimated to be 28,580 mt ( 63.0 million lb; CV = 15\%).

The SFWG noted that the recommended SSBMSY proxy is 8\% lower than the 2013 SAW57 value, even though the adult stock sizes and recruitment estimated by the F2018_BASE_V2 model run used as the basis for stock status have increased due to the inclusion of the calibrated MRIP estimates of recreational catch. Table A91 and Figure A207 show how the changes in mean weights and selectivity have impacted the SSBR, Percent MSP, and YPR 2018 calculations. These combined factors result in 'flatter' (i.e., lower slope through F35\%) SSBR at F and Percent MSP (and also YPR) at F curves in the 2018 calculations when compared to the previous 2013 SAW57 benchmark. In particular, the SSBR estimate is $25 \%$
lower, so even though the long-term median recruitment is $26 \%$ higher, at the higher F rate the resulting projected SSB35\% is 8\% lower.

An 'alternative' set of BRPs and OFL projections was developed under the assumption that recent below-average recruitment estimated for 2011-2017 (scenario R7: median of 36 million age 0 fish) will persist into the future. As noted in TOR3, however, the driver of these low recruitment events has not been identified, and so these BRPs are considered an alternative, but not recommended, illustration of potential stock productivity should below average recruitment persist into the future. The alternative BRP estimates are MSY $=10,920 \mathrm{mt}$ ( 24.074 million lb; CV $=15 \%$ ) and SSBMSY $=39,079 \mathrm{mt}$ ( 86.154 million lb ; CV $=15 \%$; Table A91). The alternative biomass threshold of $1 / 2$ SSBMSY was estimated to be $19,540 \mathrm{mt}$ ( 43.1 million lb; CV = 15\%).

TOR A6. Make a recommendation ${ }^{\text {a }}$ about what stock status appears to be, based on the existing model (i.e., model from previous peer reviewed accepted assessment) and with respect to a new modeling approach(-es) developed for this peer review.
a. Update the existing model with new data and make a stock status recommendation (about overfished and overfishing) with respect to the existing BRP estimates.
b. Then use the newly proposed modeling approach(-es) and make a stock status recommendation with respect to "new" BRPs and their estimates (from TOR-5). c. Include descriptions of stock status based on simple indicators/metrics (e.g., ageand size-structure, temporal trends in population size or recruitment indices, etc.).
${ }^{\text {a }}$ NOAA Fisheries has final responsibility for making the stock status determination for this stock based on best available scientific information.

## 2018 STOCK STATUS

## a. Old (Existing) Model and Reference Points

Model run F2018 is the 2013 SAW 57 ASAP model (2 fleets, ALB indices) with 'Old' MRIP data through 2017 and provides estimates appropriate to compare with the old (existing) reference points, which are the threshold fishing mortality FMSY proxy $=\mathrm{F} 35 \%=0.309$, target biomass SSBMSY proxy $=$ SSBMSY35\% $=62,394 \mathrm{mt}$, and threshold biomass $1 / 2$ SSBMSY proxy $=1 / 2$ SSBMSY35\% = 31,197 mt (TOR 6a). This 'old' model indicates that F in $2017=$ 0.244 and SSB in $2017=34,350 \mathrm{mt}$, so the stock was not overfished and overfishing was not occurring.

## b. New (Updated) Model and Reference Points

## Recommended Reference Points

Model run F2018_BASE_V2 is the final ASAP model adopted by the 2018 SAW-66 SFWG for the evaluation of stock status. The 2018 SAW-66 SFWG recommends that the summer flounder stock was not overfished and overfishing was not occurring in 2017 relative to the recommended biological reference points updated in this benchmark assessment. The fishing mortality rate was estimated to be 0.334 in 2017, $25 \%$ below the recommended threshold fishing mortality reference point $=\mathrm{FMSY}=\mathrm{F} 35 \%=0.448$. SSB was estimated to be $44,552 \mathrm{mt}=$ 98.220 million lb in 2017, $78 \%$ of the recommended target biomass reference point $=$ SSBMSY $=$ SSB35\% $=57,159 \mathrm{mt}(126.014$ million lb ) and $56 \%$ above the recommended threshold biomass of $1 ⁄ 2$ SSBMSY $=1 / 2$ SSBMSY35\% $=28,580 \mathrm{mt}$ ( 63.0 million lb; Table A92, Figure A208).

Fishing mortality on the fully selected age 4 fish ranged between 0.744 and 1.622 during 1982-1996 and then decreased from 0.758 in 1997 to 0.245 in 2007. Since 2007 the fishing mortality rate has increased and was 0.334 in 2017, $75 \%$ of the 2018 SAW-66 FMSY proxy $=$ $\mathrm{F} 35 \%=0.448$ (Figure A209). The $90 \%$ confidence interval for F in 2017 was 0.276 to 0.380 . Spawning stock biomass (SSB) decreased from 30,451 mt in 1982 to 7,408 mt in 1989 and then
increased to 69,153 mt in 2003. SSB has decreased since 2003 and was estimated to be 44,552 in 2017, 78\% of the 2018 SAW-66 SSBMSY proxy = SSB35\% = 57,159 mt, and 56\% above the 2018 SAW-66 $1 / 2$ SSBMSY proxy $=1 / 2$ SSB35\% = 28,580 mt (Figure A210). The $90 \%$ confidence interval for SSB in 2017 was 39,195 to $50,935 \mathrm{mt}$. The 1982 and 1983 year classes are the largest in the assessment time series, at 82 and 102 million fish, while the 1988 year class is the smallest at only 12 million fish. The average recruitment from 1982 to 2017 is 53 million fish at age 0 . Recruitment has been below average since 2010, ranging from 29 to 52 million and averaging 38 million fish (Figures A210-A211). The survival of summer flounder recruits, expressed as the R/SSB ratio, was higher in the 1980s and early 1990s than in the years since 1996 (Figure A212).

## Alternative Reference Points

Under the alternative biological reference points that have been developed in this benchmark assessment, the 2018 SAW-66 SFWG notes that the summer flounder stock was not overfished and overfishing was not occurring in 2017. The fishing mortality rate was estimated to be 0.334 in 2017, 25\% below the alternative (also new recommended) threshold fishing mortality reference point $=\mathrm{FMSY}=\mathrm{F} 35 \%=0.448$. SSB was estimated to be $44,552 \mathrm{mt}=$ 98.220 million lb in 2017, $14 \%$ above the alternative target biomass reference point = SSBMSY $=$ SSB35\% = 39,079 mt ( 86.154 million lb) and 2.28 times the alternative threshold biomass of $1 / 2$ SSBMSY $=1 / 2$ SSBMSY35\% = 19,540 mt (43.1 million lb; Table A92).

## c. Stock status based on simple indicators/metrics

The age structure of the total catch (Figure A4) and NEFSC trawl surveys (Figures A24A25) has expanded since the late 1990s when few fish were caught over age-4 and catch rates were relatively low. Most aggregate survey indices showed increasing trends from the late 1990s through the mid-2000s (Figures A23, A29, A31, A32, A34, and A37). These metrics indicate that the reduction in fishing mortality that occurred through the F reduction/stock rebuilding plan kept total mortality from all sources $(\mathrm{M}+\mathrm{F})$ low enough to allow the abundance as indicated by the surveys to increase and the age-structure to expand.

However, since the mid-2000s, most aggregate survey indices of abundance and/or biomass have remained stable or declined. This decline suggests the total mortality is too high to maintain an increasing stock trend. The exact cause of the observed trend is difficult to determine. Although recruitment indices have been below average in the most recent years (Figures A26, A30, A33, A35, A36, and A38), the driver of this pattern has not been identified nor is it clear if this pattern will persist in the future. There are also observed declines in the mean weights-at-age for both sexes and the age of maturity for age- 1 fish, but no observed changes in the length-weight relationship or fish condition indices (Fulton’s K). The observed shift in spatial distribution northward and eastward along shelf has continued since the mid2000s, during a time of both abundance increase and during the recent declines. Other sources of unaccounted for mortality or changes in fishing pressure or exploitation patterns could be contributing factors. Regardless of cause, declines in survey indices suggest that current mortality from all sources is greater than current recruitment inputs to the stock. If recruitment improves, current catches may allow the stock to increase, but if recruitment remains low or decreases further, then reductions in catch will be necessary.

TOR A7. Develop approaches and apply them to conduct stock projections.
a. Provide numerical annual projections (5 years) and the statistical distribution (i.e., probability density function) of the catch at $F_{\text {msy }}$ or an $F_{\text {msy }}$ proxy (i.e. the overfishing level, OFL) (see Appendix to the SAW TORs). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F, and probabilities of falling below threshold BRPs for biomass. Use a sensitivity analysis approach in which a range of assumptions about the most important uncertainties in the assessment are considered (e.g., terminal year abundance, variability in recruitment).
b. Comment on which projections seem most realistic. Consider the major uncertainties in the assessment as well as sensitivity of the projections to various assumptions. Identify reasonable projection parameters (recruitment, weight-atage, retrospective adjustments, etc.) to use when setting specifications.
c. Describe this stock's vulnerability (see "Appendix to the SAW TORs") to becoming overfished, and how this could affect the choice of ABC.

## INTRODUCTION

Stochastic projections were made to provide forecasts of stock size and catches in 20192023 consistent with the new (updated) 2018 SAW-66 biological reference points. The projections assume that recent (2013-2017) patterns of fishery selectivity, discarding, maturity at age and mean weight at age will continue over the time span of the projections. The projections assume that $100 \%$ of the 2018 ABC ( $5,999 \mathrm{mt}=13.226$ million lb) will be caught. The SFWG noted that these projections are essentially 'placeholders' pending the availability of calibrated ('New’) MRIP estimates for recreational catch in 2018. The SFWG did not make a quantitative assumption of the magnitude of the 2018 recreational (and therefore total) catch, but noted that it would likely be higher than the 'Old’ 2018 estimate, and therefore the current 'placeholder' 2018 ABC likely is an underestimate of the final 2018 catch. The SFWG made two sets of OFL projections, based on the recommended and alternative biological reference points (BRPs) estimated for TOR6, that differ in the magnitude of recruitment assumed for the future. The SFWG considered the 'recommended' BRPs and OFL projections to be the 'most realistic.'

## PROJECTIONS USING RECOMMENDED BRPs

The OFL projection uses F2019-F2023 = FMSY proxy $=$ F35\% = 0.448 and samples from the estimated recruitment for 1982-2017 (scenario R36: median recruitment $=51$ million age 0 fish). The recommended OFL catches are 14,208 mt in 2019 (CV = 12\%), 14,040 mt in 2020 (CV = 11\%), 14,411 mt in 2021 (CV = 11\%), 14,912 in 2022 (CV=13\%), and 15,335 in 2023 (CV=15\%; Table A93). For projections at the fixed FMSY proxy $=\mathrm{F} 35 \%=0.448$, there is $0 \%$ probability of exceeding the fishing mortality threshold and $0 \%$ probability of falling below the biomass threshold during 2019-2023. The projection results presented have a realistic probability of being achieved, and the summer flounder stock has a low vulnerability to becoming overfished, given current status and the management regime in place.

## USING ALTERNATIVE BRPs

The OFL projection uses F2019-F2023 = FMSY proxy $=$ F35\% = 0.448 and samples from the estimated recruitment for 2011-2017 (median recruitment = 36 million age 0 fish). The alternative OFL catches are 14,175 mt in 2019 (CV = 13\%), 13,783 mt in 2020 (CV = 11\%), $13,402 \mathrm{mt}$ in 2021 (CV= 10\%), 12,790 mt in 2022 (CV = 9\%), and 12,082 mt in 2023 (CV = 9\%; Table A93). For projections at the fixed FMSY proxy $=\mathrm{F} 35 \%=0.448$, there is $0 \%$ probability of exceeding the fishing mortality threshold and 0\% probability of falling below the biomass threshold during 2019-2023. The projection results presented have a realistic probability of being achieved, and the summer flounder stock has a low vulnerability to becoming overfished, given current status and the management regime in place.

TOR A8. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in most recent SARC reviewed assessment and review panel reports and MAFMC SSC reports. Identify new research recommendations.

SFWG responses to each of these recommendations are given in italics.

### 8.1. 2013 SARC 57 RESEARCH RECOMMENDATIONS

1) Continued evaluation of natural mortality and the differences between males and females. This should include efforts to estimate natural mortality, such as through markrecapture programs and telemetry.

Other than estimation of natural mortality within modeling frameworks by some of the supportive models described under TOR4, no additional empirical methods to estimate natural mortality have been conducted. The SFWG recommends this be removed, as this is not considered an urgent research issue.
2) Further work examining aspects that create greater realism to the summer flounder assessment (e.g., sexually dimorphic growth, sex-specific F, differences in spatial structure [or distribution by size?] should be conducted. This could include:
a) Simulation studies to determine the critical data and model components that are necessary to provide reliable advice, and need to determine how simple a model can be while still providing reliable advice on stock status for management use, and should evaluate both simple and most complex model configurations.
b) Development of models incorporating these factors that would create greater realism.
c) These first steps (a or b) can be used to prioritize data collection, and determine if additional investment in data streams (e.g., collection of sex at age and sex at length and maturity data from the catch, additional information on spatial structure and movement, etc.) are worthwhile in terms of providing more reliable assessment results.
d) The modeling infrastructure should be simultaneously developed to support these types of modeling approaches (flexibility in model framework, MCMC/bootstrap framework, projection framework).

Some progress has been made (for b) as demonstrated in the development of sex-specific supportive models for this assessment described under TOR4. Gains in the reliability of advice produced from the inclusion of sex specific complexity have not been shown (for a or b), with the sex-specific supportive models providing similar overall results/advice to the primary assessment model presented. Some fine scale and regional analyses have been conducted that examine the distribution and movement by sex (for c), as well as distribution of adults and recruits along the shelf, which has provided some insight into the complexity of patterns in movement for this species (see TOR3). Work will continue in the future by different researchers on these topics for future SAWs.
3) Develop comprehensive study to determine the contribution of summer flounder nursery area to the overall summer flounder population, based off approaches that are similar to those
developed in 2013 SAW 57 WPA12.
WPA12 noted above recommended that work be done to identify contributions to nursery areas utilizing otolith microchemistry. While the work has not yet been published, Joel Fodrie at the University of North Carolina is conducting work using otolith microchemistry, and Jennifer Hoey at Rutgers University, NJ has conducted work using genetic markers. The SFWG recommends this be removed and replaced with the new, more broadly focused SFWG recommendation \#1.
4) Develop an ongoing sampling program for the recreational fishery landings and discards (i.e., collect age, length, sex) to develop appropriate age-length keys for ageing the recreational catch.

No ongoing, synoptic sampling program has been developed, although comprehensive data collections were conducted in 2010-2012 and 2016 by Jason Morson and Daphne Munroe at Rutgers University, NJ.
5) Apply standardization techniques to all of the state and academic-run surveys, to be evaluated for potential inclusion in the assessment.

Significant progress has been made by the SFWG during this assessment under TOR2 to explore these approaches and develop sensitivity analyses to the primary assessment model, although ongoing work to improve treatment of age composition in the aggregated indices and estimation of uncertainty is needed.
6) Continue efforts to improve understanding of sexually dimorphic mortality and growth patterns. This should include monitoring sex ratios and associated biological information in the fisheries and all ongoing surveys to allow development of sex-structured models in the future.

These continue to be monitored in at least the NEFSC, NEAMAP, and MADMF trawl surveys as described under TOR2.
7) Conduct sensitivity analyses to identify potential causes of the recent retrospective pattern. Efforts should focus on identifying factors in both survey and catch data that could contribute to the decrease in cohort abundance between initial estimates based largely on survey observations and subsequent estimates influenced by fishery dependent data as the cohort recruits to the fishery.

Progress has been made. The recent retrospective is negligible in the SAW-66 assessment as shown under TOR4. The inclusion of substantially higher catch in the recreational fleet time series resulting from the revised estimates is a contributing factor for this change. The SFWG recommends this be removed because it is no longer an issue.
8) Develop methods that more fully characterize uncertainty and ensure coherence between assessments, reference point calculation and projections.

This recommendation is unclear as written to original intent (even to SFWG members who were
in the room when it was originally written. The SFWG recommends this be removed and replaced with new SFWG recommendation \#2.

### 8.2 MAFMC SSC 2013-2018 RESEARCH RECOMMENDATIONS

1) Evaluate uncertainties in biomass to determine potential modifications to OFL CV employed.

The SFWG was unable to recommend an OFL CV modification, and there is not a strong analytical basis for any adjustment to the OFL CV. The calculated assessment OFL CVs for 2019-2023 range from 11\%-14\% (TOR 7).

The MAFMC SSC (Paul Rago) has work in progress to provide options for alternative quantitative calculations of the OFL CV.
2) Evaluate fully the sex- and size distribution of landed and discarded fish, by sex, in the summer flounder fisheries.

See the SFWG response above under section 8.1, recommendation \#4.
3) Evaluate past and possible future changes to size regulations on retention and selectivity in stock assessments and projections.

The SFWG has explored this issue and recommends it be removed. In this assessment, changes in the selectivity of the fleets in response to regulation was examined and tested using different time blocks.
4) Incorporate sex-specific differences in size at age into the stock assessment.

Sex specific differences were incorporated and tested in the supportive modeling approaches presented under TOR4. Also see the SFWG response above under section 8.1, recommendation \#4 and \#6.
5) Determine and evaluate the sources of the over-optimistic stock projections.

This recommendation has been explored over the last few years, with results presented to the MAMFC SSC (Paul Rago analyses); however, with newly calibrated recreational catch estimates ('New' MRIP) included in the assessment, a new baseline for projection performance must be established and evaluated in the future.
6) Evaluate the causes of decreased recruitment and changes in recruitment per spawner in recent years.

Some progress has been made by the SFWG in describing potential causes for recent below average recruitment. However, understanding and verifying the mechanisms that may be causing the observed patterns warrants further research. Under TOR3, factors causing the shifts in the distribution of recruits and changes in habitat use/availability by early life stage are identified as
two areas to be considered for further work.
7) Explore if and how changes in distribution and movement of the summer flounder stock may affect survey indices and fishery performance.

Substantial progress has been made by the SFWG under TORs 1, 2, and 3. This SAW-66 assessment examined information on the changing distribution of the fishery (under TOR1), explored survey catch rates spatially and factors effecting relative efficiency (such as diel sampling) under (TOR2), conducted work to aggregate indices using habitat occupancy information (TOR2), and examined changes in distribution and movement in response to environmental factors under TOR3. This recommendation has been fully explored and the SFWG recommended it be removed.

### 8.3. NEW 2018 SARC-66 RESEARCH RECOMMENDATIONS

1) Continue to explore changes in the distribution of recruitment. Develop studies, sampling programs, or analyses to better understand how and why these changes are occurring, and the implications to stock productivity.
2) The reference points are internally consistent with the current assessment. It may be useful to carry uncertainty estimates through all the components of the assessment, BRPs, and projections.
3) Explore the potential mechanisms for recent slower growth that is observed in both sexes.

## Process recommendation

Provide an opportunity for the NMFS stock assessment scientists and Council SSCs to meet in person to promote common understanding of how the assessment products are used and considered in the process of developing SSC acceptable biological catch (ABC) limit advice for the Councils. The intent of this meeting is to align expectations and find opportunities to improve products and the process for both groups.

This page is left intentionally blank

## ACKNOWLEDGMENTS

Special thanks to Eric Robillard and the staff of the NEFSC Population Biology Branch for their timely preparation of the 2017 NEFSC summer flounder commercial fishery and research survey ages used in the assessment.

Special thanks also goes to Alicia Miller of the NEFSC Population Dynamics Branch for her outstanding work in preparing the fishery and survey distribution maps presented in the assessment.

Table A37. Northeast Fisheries Science Center (NEFSC) trawl survey indices of abundance for summer flounder. Indices are stratified mean numbers (n) and weight (kg) per tow. Spring indices are for offshore strata 1-12 and 61-76; fall indices are for offshore strata 1-2, 5-6, 9-10, 61, 65, 69 and 73. Winter indices (1992-2007) are for offshore strata 1-3, 5-7, 9-11, 13-14, 16-17, 6163, 65-67, 69-71 and 73-75. Note that door and vessel conversion factors for 1967-2008 are not significant; 1967-2008 gear conversion factors have not been included due to limited sample size and extreme violation of underlying assumptions in experimental work. $\mathrm{N} / \mathrm{A}=$ not available due to incomplete coverage (spring) or end of survey (winter).

Table A38. Northeast Fisheries Science Center (NEFSC) spring and fall trawl survey indices from the FSV HB Bigelow (BIG) and aggregate calibrated, equivalent indices for the FSV Albatross IV (ALB) time series. Indices are stratified mean numbers ( n ) and weight (kg) per tow. Spring indices are for offshore strata 1-12 and 61-76; fall indices are for offshore strata 1-2, 5-6, 9-10, 61, 65, 69 and 73 . The aggregate spring catch number calibration factor is 3.2255 ; the spring catch weight factor is 3.0657 ; the fall catch number factor is 2.4054 ; the fall catch weight factor is 2.1409. Indices compiled using SHG acceptance criteria. No survey data available ( $\mathrm{n} / \mathrm{a}$ ) for fall 2017.

Table A39. Northeast Fisheries Science Center (NEFSC) trawl survey spring and fall survey indices from the FSV HB Bigelow (BIG) and length calibrated, equivalent indices for the FSV Albatross IV (ALB) time series. Indices are the sum of the stratified mean numbers (n) at length. Spring strata set includes offshore strata 1-12, 61-76. Fall strata set (aged set) includes offshore strata $1,5,9,61,65,69,73$, and inshore strata 1-61. The BIG does not sample the shallowest inshore strata ( $0-18 \mathrm{~m} ; 0-60 \mathrm{ft} ; 0-10$ fathoms). The length calibration factors are for the lengths observed in the 2008 calibration experiment and include a constant swept area factor of 0.579 . The effective total catch number calibration factors (BIG/ALB ratios) vary by year and season, depending on the characteristics of the BIG length frequency distributions. Indices compiled using SHG acceptance criteria. No survey data available (n/a) for fall 2017.

Table A51. Northeast Fisheries Science Center (NEFSC) trawl survey spring survey indices at age from the FSV HB Bigelow (BIG). Spring strata set includes offshore strata 1-12, 61-76. 'Standard' indices compiled using TOGA acceptance criteria. 'Absolute' indices are compiled using efficiency estimates at length from 'sweep-study' experiments. 'Swept Area Numbers' (SWAN) indices are compiled using efficiency estimates at length from 'twin trawl sweep study' experiments, average wing-spread dimension, average tow speed, and annual survey area to provide estimates of absolute population size.

Table A52. Northeast Fisheries Science Center (NEFSC) trawl survey fall survey indices at age from the FSV HB Bigelow (BIG). Fall strata set includes offshore strata 1, $5,9,61,65,69,73$, and inshore strata 1-61. The BIG does not routinely sample the shallowest inshore strata ( $0-18 \mathrm{~m} ; 0-60 \mathrm{ft} ; 0-10$ fathoms). 'Standard' indices compiled using TOGA acceptance criteria. 'Absolute' indices are compiled using efficiency estimates at length from 'sweep-study' experiments. 'Swept Area Numbers' (SWAN) indices are compiled using efficiency estimates at length from 'sweep-study' experiments, average wing-spread dimension, average tow speed, and annual survey area to provide estimates of absolute population size. No survey data available (n/a) for fall 2017.

Table A52 continued. Northeast Fisheries Science Center (NEFSC) trawl survey fall survey indices at age from the FSV HB Bigelow (BIG). Fall strata set includes offshore strata $1,5,9,61,65,69,73$, and inshore strata 1-61. The BIG does not routinely sample the shallowest inshore strata ( $0-18 \mathrm{~m} ; 0-60 \mathrm{ft}$; 0-10 fathoms). 'Standard' indices compiled using TOGA acceptance criteria. 'Absolute' indices are compiled using efficiency estimates at length from 'sweep-study' experiments. 'Swept Area Numbers' (SWAN) indices are compiled using efficiency estimates at length from 'sweep-study' experiments, average wing-spread dimension, average tow speed, and annual survey area to provide estimates of absolute population size. No survey data available (n/a) for fall 2017.

Table A68. Virginia Institute of Marine Science (VIMS) Chesapeake Bay Multispecies Monitoring and Assessment Program (ChesMMAP) trawl survey indices for summer flounder. Top: aggregate indices are delta-lognormal model geometric means per tow. Bottom: aged indices are in numbers, are compiled independently, and are aged using a smoothed age-length key, and so do not total to the aggregate numeric indices in the top table.

| Year | Number (CV \%) | Biomass (CV \%) |
| ---: | ---: | ---: |
| 2002 | $120.3(27)$ | $53.6(24)$ |
| 2003 | $35.4(30)$ | $11.8(29)$ |
| 2004 | $45.8(25)$ | $17.4(20)$ |
| 2005 | $150.1(21)$ | $56.1(19)$ |
| 2006 | $176.6(26)$ | $62.3(22)$ |
| 2007 | $117.0(34)$ | $38.8(29)$ |
| 2008 | $86.4(29)$ | $30.4(25)$ |
| 2009 | $35.1(30)$ | $15.7(25)$ |
| 2010 | $36.6(29)$ | $15.6(24)$ |
| 2011 | $23.2(28)$ | $14.1(26)$ |
| 2012 | $3.1(32)$ | $1.6(29)$ |
| 2013 | $4.1(39)$ | $1.8(31)$ |
| 2014 | $3.2(39)$ | $1.6(28)$ |
| 2015 | $5.2(32)$ | $2.8(32)$ |
| 2016 | $3.0(32)$ | $1.7(32)$ |
| 2017 | $3.2(41)$ | $1.7(35)$ |

| Year | 0 | 1 | 2 | 3 | $4+$ | Total |
| :---: | :---: | :---: | :---: | :---: | :---: | ---: |
| 2002 | 59.0 | 19.3 | 5.6 | 3.7 | 4.6 | 92.1 |

Table A93. 2018 Summer flounder SAW-66 benchmark assessment OFL Projections for 2019-2023. Projections using the 2018 SAW-66 benchmark assessment model (data through 2017) were made to estimate the OFL catches for 2019-2023. The projections assume that $100 \%$ of the 2018 ABC ( $5,999 \mathrm{mt}=13.226$ million lb) will be caught. The OFL projection uses F2019-F2023 $=$ FMSY proxy $=\mathrm{F} 35 \%=0.448$. The recommended catches (top table) are from projections that sample from the estimated recruitment for 1982-2017 (R36; median = 51 million). The alternative catches (bottom table) are from projections that sample from the estimated recruitment for 2011-2017 (R7: median $=36$ million).

R36: The OFL projection uses F2019-F2023 $=$ FMSY proxy $=$ F35\% $=0.448$ and samples from the estimated recruitment for 1982-2017 (median $\mathbf{R}=51$ million; $\operatorname{SSB} 35 \%=57,159 \mathrm{mt}$ ).

OFL Total Catch, Landings, Discards, Fishing Mortality (F) and Spawning Stock Biomass (SSB) in 2018-2023

Catches and SSB in metric tons

| Year | Total Catch | Landings | Discards | F | SSB |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  |  |
| 2018 | 5,999 | 4,628 | 1,371 | 0.194 | 49,827 |
| 2019 | 14,208 | 10,832 | 3,376 | 0.448 | 50,922 |
| 2020 | 14,040 | 10,567 | 3,473 | 0.448 | 52,323 |
| 2021 | 14,411 | 10,830 | 3,581 | 0.448 | 53,783 |
| 2022 | 14,912 | 11,261 | 3,651 | 0.448 | 54,877 |
| 2023 | 15,335 | 11,605 | 3,730 | 0.448 | 55,724 |

R7: The OFL projection uses F2019-F2023 = FMSY proxy $=$ F35\% $=0.448$ and samples from the estimated recruitment for 2011-2017 (median $\mathbf{R}=36$ million; $\operatorname{SSB} 35 \%=$ 39,079 mt).

OFL Total Catch, Landings, Discards, Fishing Mortality (F) and Spawning Stock Biomass (SSB) in 2018-2023

Figure A201. Comparison of the fishing mortality (top panel) and Spawning Stock Biomass (bottom panel) results from the 2008 SAW 47 benchmark assessment, the 2009-2012 assessment updates, 2013 SAW 57 benchmark assessment, the 2015-2016 assessment updates, the existing ('Old’) model updated through 2017 with ‘Old’ MRIP (F2018_OLD_MODEL), and the final F2018_BASE_V2 model with 'New' MRIP (F2018_BASE_NEW) for the 2018 SAW-66 assessment.

Figure A202. Comparison of the estimated stock numbers for age 0 (model age 1) from the 2008 SAW-47 benchmark assessment, the 2009-2012 assessment updates, 2013 SAW-57 benchmark assessment, the 2015-2016 assessment updates, the existing ('Old’) model updated through 2017 with ‘Old’ MRIP (F2018_OLD_MODEL), and the final F2018_BASE_V2 model with 'New' MRIP (F2018_BASE_NEW) for the 2018 SAW-66 assessment.

## Summer Flounder Historical Retrospective 1990-2018 Stock Assessments

Figure A203. Historical retrospective of the 1990-2018 stock assessments of summer flounder. Note that F for the 1990-2007 assessments is reported for ages 2-7+, F for the 2008-2012 assessments is reported for ages 3-7+, while F for the 2013-2018 assessments is reported for age
4.

Figure A204. Comparison of spawning stock biomass from other non-preferred models to the ASAP_BASE_V2 final model configuration.

Figure A205. Comparison of fishing mortality from other non-preferred models to the ASAP_BASE_V2 final model configuration. Note: Because of Stock Synthesis use of domeshaped, time-varying selectivity, it is not shown here.

Figure A206. Patterns in Spawning Stock Biomass (SSB) mean weights at age (top), fishery selectivity at age (middle), and maturity at age (bottom) in the 2013 SAW-57 and 2018 SAW-66 summer flounder stock assessments.

Figure A207. Patterns in Spawning Stock Biomass per Recruit (SSB/R; top), percent Maximum Spawning Potential (Percent MSP; middle), and Yield per Recruit (YPR; bottom) in the 2013 SAW-57 and 2018 SAW-66 summer flounder stock assessments.

Figure A208. Estimates of summer flounder spawning stock biomass (SSB) and fully-recruited fishing mortality (F, peak at age 4) relative to the 2018 SAW-66 recommended biological reference points. Filled circle with $90 \%$ confidence intervals shows the assessment point estimates. The open circle shows the retrospectively adjusted estimates.

Figure A209. Total fishery catch (metric tons; mt; solid line) and fully-recruited fishing mortality (F, peak at age 4; squares) of summer flounder. The horizontal solid line is the 2018 SAW-66 recommended fishing mortality reference point proxy FMSY $=\mathrm{F} 35 \%=0.448$.

Figure A210. Summer flounder spawning stock biomass (SSB; solid line) and recruitment at age 0 (R; vertical bars) by calendar year. The horizontal dashed line is the 2018 SAW-66 recommended target biomass reference point proxy, SSBMSY $=$ SSBF35\% $=57,159 \mathrm{mt}$. The horizontal solid line is the 2018 SAW-66 recommended threshold biomass reference point proxy $1 / 2$ SSBMSY $=1 / 2$ SSBF35\% $=28,580 \mathrm{mt}$.

Figure A211. Stock-recruitment (SSB-R) scatter plot for the summer flounder 1983-2017 year classes. The largest recruitment ( R ) point is the 1983 year class ( $\mathrm{R}=102$ million, $\mathrm{SSB}=30,451$ $\mathrm{mt})$. The lowest recruitment point is for the 1988 year class ( $\mathrm{R}=12$ million, $\mathrm{SSB}=22,913 \mathrm{mt}$ ). The 2017 year class is at $\mathrm{R}=42$ million, $\mathrm{SSB}=43,000 \mathrm{mt}$.

Figure A212. Recruits per Spawning Stock Biomass ratio (R/SSB) plot indicative of the relative survival of the summer flounder 1983-2017 year classes.

## A. Summer flounder Appendix 1: In-meeting Analyses for the SARC

1) The SARC was interested in seeing the time series of partial Fs for the four fishery fleets plotted to see if peaks and valleys line up, to explore how much consistency there is in the landings and discards Fs estimated by year. A second presentation was compiled in which the partial Fs are weighted by the fleet total catch numbers. Both of the following plots were prepared and presented to the SARC. The SARC and working group members discussed the reasons why the patterns in landings and discards might not closely match. For the commercial fishery, discards are often regulatory in nature, rather than strictly reflective of the magnitude of directed effort and landings, and both landings and discards integrate the differing selection patterns of multiple gears. For the recreational fishery, the discards are driven strongly by annually varying state-mandated regulations. For both fisheries, discards can be high in years of strong recruitment, and therefore inconsistent with the fishery quotas and realized landings.

1

2
2) The SARC requested some models runs for which the catch CV ( 0.10 on all 4 fleets) was increased to explore the robustness of the model results when the model fit to the catch is relaxed. Alternatives models with $\mathrm{CV}=0.20$ and 0.30 were run and the comparative results presented to the SARC (figures below). The SARC concluded that the model was robust to alternative catch weightings, and suggested that this type of sensitivity be performed for future assessments.

| F2018_BASE_V2 |  |  |  |
| :---: | :---: | :---: | :---: |
| Fleets | All CV $=0.1$ | All CV $=0.2$ | All CV $=0.3$ |
| 1988 F | 1.62 | 1.66 | 1.67 |
| 1995 F | 1.45 | 1.21 | 1.02 |
| 2013 F | 0.45 | 0.52 | 0.61 |
| 2017 F | 0.33 | 0.33 | 0.32 |
| 1988 SSB | 12572 | 11974 | 11877 |
| 1995 SSB | 21103 | 21379 | 21955 |
| 2013 SSB | 56052 | 54789 | 54050 |
| 2017 SSB | 44552 | 45726 | 47796 |
| Frho | -4\% | -9\% | -13\% |
| SSB rho | +2\% | +5\% | +7\% |
| Age 0 rho | +2\% | +4\% | +5\% |
