# Bluefish 2011 Stock Assessment Update 

Coastal/Pelagic Working Group
Northeast Fisheries Science Center
National Marine Fisheries Service

Woods Hole, MA

June 2011

## Executive Summary

The updated stock assessment was completed by adding catch and indices through 2010 to the previous 1982-2009 assessment. Catch information consisted of commercial landings and length frequencies from Maine to Virginia collected by the Northeast Fisheries Science Center, North Carolina landings and length information collected by NC Division of Marine Fisheries, Florida landings and length information collected by FL Fish and Wildlife Research Institute, and recreational landings and discards from Maine to Florida collected in the NMFS recreational fisheries survey. The catch data were combined with fisheries independent survey data from the Northeast Fisheries Science Center, DE DNR, NJ DEP, CT DEP, coast-wide recreational catch per angler, as well as juvenile indices from the SEAMAP program in the South Atlantic, in a forward projecting catch at age model (ASAP). Fishery dependent and independent information was partitioned into ages using a 2010 age-length key developed by Old Dominion University.

The result of the analysis shows that bluefish is not overfished or experiencing overfishing. Fishing mortality in 2010 was 0.14 , below the biological reference point ( $\mathrm{F}_{\mathrm{MSY}}$ ) of 0.19 . Fishing mortality steadily declined from 0.34 in 1987 to 0.12 in 1999 and has remained steady since 2000 with an average $\mathrm{F}=0.14$. Recent total stock biomass estimates peaked in 1982 at 318.2 thousand MT, then declined to 79.6 thousand MT by 1996 before increasing to the 2010 level of 140.3 thousand MT. Recruitment estimated in the ASAP model has remained relatively constant since 2002 at around 21.4 million age-0 bluefish, with the exception of a relatively large 2006 cohort estimated as 37.3 million fish. However, the 2009 and 2010 recruitment estimates were well below average at 11.2 and 6.7 million fish, respectively. There was no significant retrospective bias in the results. A projection of the abundance through 2013, under five different fishing scenarios between $\mathrm{F}=0.10$ and $\mathrm{F}=0.19$, suggest that continue to biomass will decline due to poor incoming year classes. Changes in the NMFS survey, limited age information, discard size data and model configuration all contribute to the uncertainty in the assessment.

## Introduction

The Atlantic coast stock of bluefish (Pomatomus saltatrix), distributed from Maine through eastern Florida, is jointly managed by the Atlantic States Marine Fisheries Commission (ASMFC) and the Mid-Atlantic Fishery Management Council (MAFMC). A total annual quota is established and allocations given to commercial and recreational fisheries. The management plan requires a distribution of $80 \%$ to recreational and $20 \%$ to commercial, with provisions to shift unused recreational quota to commercial fisheries.

A bluefish stock assessment was presented for peer-review at the Northeast Fisheries Science Center Stock Assessment Review Committee meeting (NEFSC SARC 41). The reviewers accepted the assessment for use in management decisions although there were some reservations about the modeling approach. Since the review, the bluefish stock assessment sub-committee (SASC) has produced annual updates while maintaining the basic model settings from the approved assessment. The current assessment is a continuation of the model update with the addition of 2010 catch at age and indices at age information.

## Life History

Bluefish, Pomatomus saltatrix, is a coastal, pelagic species found in temperate and tropical marine waters throughout the world (Goodbred and Graves 1996; Juanes et al. 1996). Bluefish spawn in offshore waters (Kendall and Walford 1979; Kendall and Naplin 1981). Larvae develop into juveniles in continental shelf waters and eventually move to estuarine and nearshore shelf habitats (Marks and Conover 1993; Hare and Cowen 1994; Able and Fahay 1998; Able et al. 2003). Bluefish are highly migratory along the U.S. Atlantic coast and seasonally move between the U.S. south Atlantic and Middle-Atlantic, traveling as far north as Maine (Shepherd et al., 2006).

Several studies show bluefish to be a moderately long-lived fish with a maximum age of 14 years (Hamer 1959; Lassiter 1962; Richards 1976; Barger 1990; Chiarella and Conover 1990; Terceiro and Ross 1993; Austin et al. 1999; Salerno et al. 2001; Sipe and Chittenden 2002). Bluefish up to 88 centimeter (cm) fork length (FL) have been aged (Chiarella and Conover 1990; Salerno et al. 2001), although Terceiro and Ross (1993)
noted considerable variation in mean bluefish size-at-age. Scale ages have been used to estimate von Bertalanffy growth parameters (Lassiter 1962; Barger 1990; Terceiro and Ross 1993; Salerno et al. 2001). The values for $\mathrm{L}_{\infty}$ from these studies ( $87-128 \mathrm{~cm}$ FL) match closely to the largest individuals in catch data and growth rates do not differ between sexes (Hamer 1959; Salerno et al. 2001).

Bluefish grow nearly one-third of their maximum length in their first year (Richards 1976, Wilk 1977). Variation in growth rates or sizes-at-age among young bluefish is evident from the appearance of intra-annual cohorts. Lassiter (1962) identified a spring-spawned cohort and a summer-spawned cohort from the bimodal appearance of size at Annulus I for fish aged from North Carolina and the seasonal cohorts can differ in age by two to three months. Summer-spawned larvae and juveniles grow faster than spring-spawned larvae and juveniles (McBride and Conover 1991) although size differences at annual age diminish greatly after three to four years (Lassiter 1962).

Spawning occurs offshore in the western North Atlantic Ocean, from approximately Massachusetts to Florida (Norcross et al. 1974; Kendall and Walford 1979; Kendall and Naplin 1981; Collins and Stender 1987). Bluefish are characterized as multiple spawners with indeterminate fecundity which spawn continuously during their spring migration (Robillard et al. 2008). In addition to distinctive spring and summer cohorts, Collins and Stender (1987) identified a fall-spawned cohort, demonstrating the potential of an extended bluefish spawning season.

Bluefish in the western North Atlantic are managed as a single stock (NEFSC 1997; Shepherd and Packer 2006). Genetic data support a unit stock hypothesis (Graves et al. 1992; Goodbred and Graves 1996; Davidson 2002). For management purposes, the ASMFC and MAFMC define the management unit as the portion of the stock occurring along the Atlantic Coast from Maine to the east coast of Florida.

## Fisheries Dependent Data

Annual catch information was developed for five components of the commercial fishery. Commercial landings from Maine to Virginia, North Carolina commercial landings, Florida commercial landings, coast-wide recreational landings and coast-wide recreational discards.

Commercial fisheries from Maine to Virginia were sampled as part of the NEFSC data collection program. Lengths were sampled from a variety of gears and market categories. Expansion of length data was completed by market category and quarter of the year, with the results merged into half year periods. In 2010 a total of 4,930 measurements from 91 samples were collected across all market categories from total landings of $1,601 \mathrm{mt}$ ( $50 \%$ of all commercial landings; Table 1). Market category/quarter with inadequate length samples were filled with length information from adjacent quarters within the same market category or from NC samples if necessary.

North Carolina commercial landings were expanded using length samples collected by NC Division of Marine Fisheries. A total of 1,042 measurements from 24 samples were collected from landings of 1,463 mt (Table 1). Expansion of landings at length were done by quarter, market category and gear type then combined into half year totals. Length samples from Florida 2010 commercial landings were also available. A total of 706 lengths from 53 samples were used to expand commercial landings of 143 mt (Table 1). No landings were reported for South Carolina or Georgia. Total coast-wide commercial landings in 2010 were 3,206 mt, an increase of 55 mt from 2009 (Figure 1).

Length frequencies from commercial fisheries are characterized by a multi-modal distribution (Figure 2). In 2010 the distribution was strongly bimodal with one peak at 38 cm and a second around 70 cm . There were few fish below 25 cm . In comparison, the 2006 and 2008 distribution included a third mode around 55 cm . The 2009 distribution, as well as previous years, was similarly bimodal.

Recreational landings are sampled for length as part of the MRFSS program. The 2010 recreational landings were $8,184 \mathrm{mt}$, an increase from $6,161 \mathrm{mt}$ in 2009 (Table 2, Figure 3). The MRFSS 2010 length samples ( $\mathrm{N}=2,968$ ) were used to expand recreational landings per half year. Recreational discards in 2010 were estimated at $16,059 \mathrm{mt}$, however after adjusting for a $15 \%$ mortality rate, the resulting discard loss was 2,409 mt. A recent publication (Fabrizio et al 2008) shows that mortality may be higher and the $15 \%$ should be reevaluated in the next benchmark assessment. Length sampling for bluefish discards in MRFSS at-sea sampling of recreational party boats provided lengths of 195 discarded bluefish. In addition, lengths of bluefish tagged and released in the American Littoral Society tagging program (by definition B2 catches) were included in
the length distribution $(\mathrm{n}=960)$. Total combined (commercial and recreational) length frequencies are presented in Figure 5.

Age data ( $\mathrm{n}=393$ ) were provided by Virginia Marine Resources Commission and Old Dominion University ageing lab. Since the age key developed from the VA samples was the only 2010 age information available, it was applied to both fishery dependent and independent length data. Age data was provided by cm , fork length by half year. In previous years the age key was provided for fish measured to total length, inches while the length frequencies were measured in fork length to the nearest cm . Consequently, previous length frequencies were converted to TL, inches using the following equation:

$$
\mathrm{TL}(\mathrm{in})=0.245(\mathrm{FL}(\mathrm{~cm}))+0.440
$$

For the assessment update, the age keys for 2004-2010 were made available in FL, cm. Previous years data were updated (which included updating catch totals) and length frequencies expanded using the revised age-length keys. In addition, the length frequencies by age were converted to weight for calculation of annual weights at age (beginning with 2004) (Table 3 Figure 6). Length-weight equations from the spring and fall NEFSC bottom trawl survey were used for calculating weights at age. Due to low sample size in spring surveys, all years beginning with 1993 were used in the equation ( $\mathrm{n}=205$, $\mathrm{a}=-11.289, \mathrm{~b}=2.985$ ). Fall equations were estimated from combined 2004-2010 length-weight data ( $\mathrm{n}=3334, \mathrm{a}=-11.621, \mathrm{~b}=3.096$ ).

The previous catch at age through 2009 and the updated catch at age through 2010 are presented in table 4 a and 4 b . As in previous bluefish assessments the ages are summarized in a plus category for ages 6 and above to reduce the effect of aging error.

## Fisheries Independent Data

Survey indices as used in the previous bluefish assessment were updated for 2010. These indices include SEAMAP juvenile (age 1) indices, Northeast Fisheries Science Center (NEFSC) bottom trawl survey indices for ages 0 to $6+$, NJ bottom trawl survey indices of ages 0 to 2, DE bottom trawl survey indices for ages 0 to 2 and Marine Recreational Fisheries Statistics Survey (MRFSS) recreational catch per angler trip
(CPA) for ages 0 to $6+$. The CT survey in 2008 and 2010 were not conducted during the month of September, therefore these indices were treated as missing data. The NEFSC survey in 2009 was modified by the replacement of the FV Albatross IV with the FSV Henry B. Bigelow. The consequence of the replacement was a change in the areas surveyed and the efficiency of the survey due to a change in net size and towing speed (as well as other intangibles associated with a different vessel). Beginning in 2009 only the outer third of the inshore strata set was sampled by the Bigelow. In addition, a conversion coefficient of 1.16 was used to convert Bigelow mean number per tow into equivalent Albatross units (Miller et al., 2010).

Among these survey indices, there were no consistent trends in total abundance. The total NEFSC index (ln re-transformed stratified mean number per tow) declined to 6.66 in 2010 from 12.8 in 2008 (Table 5). The series arithmetic average index equaled 26.6 (geometric mean of 13.89). The 2010 Delaware survey index of ages 0 to 2 was 0.481 fish per tow, and below the time series average ( 0.520 per tow; Table 6). New Jersey trawl survey indices of ages 0 to 2 for 2010 ( 1.64 fish/tow) was also below the time series average of 6.3 per tow (Table 6). No indices of bluefish abundance in Long Island Sound from the CT DEP survey were available from 2010 however, ages 0 to $6+$ in 2009 ( 32.86 per tow) were about average for the series ( 33.42 per tow; Table 7). Recreational catch per angler trip showed a small increase to 0.978 fish per angler trip in 2010, an increase from 0.832 in 2009 (Table 8). The recreational catch per angler was modeled in a general linear model using a negative binomial error structure. The year coefficient partitioned into ages (assuming the same proportion as the recreational catch) was used in the ASAP model as a relative index of abundance.

Standardized recruitment indices (age 0) were developed using Z scores to compare the relative 2010 indices to time series averages. Indices from NEFSC, DE, NJ, and the Recreational CPA were all below average (Table 9, Figure 7).

## ASAP Model

The initial ASAP model (version 2.0.20) was run with the previous 1982-2009 input file updated for 2010 total catch, catch at age, weight at age and indices at age. The fishery was modeled as a single fleet with selectivity fixed as a bimodal pattern with full
recruitment at age 1 (coded age 2). Model weighting factors remained the same as previous assessments with the model heavily weighted towards the fishery total catch rather than survey indices. Natural mortality was fixed at 0.2 and maturity at age was held constant with full maturity at age 3 . The updated model was run using the same parameter settings while substituting the updated catch and weight at age matrices. The modifications to the input matrices had little influence on the resulting trends in population number or biomass (Appendix I).

The results of the updated ASAP model showed a decrease in total abundance since 2006, declining from 97.9 million to 72.2 million fish (Table 10, Figure 8). The decline is primarily the result of poor 2009 and 2010 year classes. Prior to 2009 and 2010, recruitment had remained relatively constant since 2000 at 21.4 million age- 0 bluefish, with the exception of a large 2006 cohort estimated as 37.3 million fish. The 2009 recruitment estimate was below average at 11.2 million fish compared to the series average of 22.8 million (Figure 9). Estimated recruitment in 2010 was the lowest in the time series at 6.7 million. However among other age groups, the estimate of age 6-plus bluefish continued to be large at 12.9 million, the second highest since 1990. Total mean biomass in 2010 equaled $140,297 \mathrm{mt}$, a slight decrease since 2009. (Figure 10, Table 11). Corresponding spawning stock biomass (SSB) in 2010 was $134,065 \mathrm{mt}$ (Figure 10). Updates to the mean weight at age has occurred in the current assessment, consequently direct comparison of biomass estimates to previous bluefish assessments updates is not appropriate.

Fishing mortality estimates in ASAP are based on a separability assumption with $F$ at age the product of $F_{\text {MULT }}$ and selectivity. Full selectivity is fixed at age 1. The 2010 $F_{\text {MULT }}$ value equals 0.14 (Figure 8). Fishing mortality steadily declined from 0.34 in 1987 to 0.12 in 1999 and has remained steady since 2000 with an average $\mathrm{F}=0.14$.

Retrospective bias for the final model was examined for F , total abundance, recruitment (age 0) and total biomass. The analysis shows little evidence of bias in the estimates (Figure 11). The variation in the final model results for F and SSB was determined using a Monte Carlo Markov chain with 1000 iterations and a thinning factor of 100 . The MCMC results of variation around F ranged from 0.114 to 0.159 , with the
$80 \%$ CI between 0.128 and 0.147 . Estimates for SSB ranged from 114,623 to 158,030 mt , with an $80 \%$ CI between $124,044 \mathrm{mt}$ and $140,788 \mathrm{mt}$. (Figure 12).

## Projections

Bluefish abundance and biomass through 2013 were examined for a range of fishing scenarios with a stochastic projection in AGEPRO software. Weight at age in 2011-2013 was assumed equal to 2010, recruitment was derived from a random draw of 28 empirical estimates of age 0 abundance since 1982 and initial population size was drawn from the output of the MCMC run. Fishing mortality for 2011 was assumed equal to targeted F of 0.15 . Five projection scenarios were examined: $\mathrm{F}=0.10, \mathrm{~F}=$ status quo (0.14) (equivalent to F equal to $75 \%$ of $\mathrm{F}_{\mathrm{MSY}}(0.14)$ ), $\mathrm{F}_{\text {target }}(0.17)$ which equals $90 \%$ of $\mathrm{F}_{\text {MSY }}$ as defined in FMP, $\mathrm{F}_{0.1}(0.16)$ from the yield per recruit, and $\mathrm{F}_{\text {MSY }}(0.19)$

Results of the projections show a decrease in mean biomass and SSB for each scenario including a reduced $\mathrm{F}(\mathrm{F}=0.10)$ (Table 12, Appendix II). However, abundance could continue to increase in all 5 cases. Yield through 2013 would be projected as lower for F scenarios of status quo or less. Under status quo F (0.14), projected 2012 yield would increase to $13,953 \mathrm{mt}$, which includes commercial and recreational landings as well as recreational discards losses.

## Biological Reference Points

The current biological reference points for bluefish were determined in SARC 41 and are $\mathrm{F}_{\text {MSY }}(0.19)$ and $\mathrm{B}_{\text {MSY }}(147,052 \mathrm{mt})$. The basis for the reference points was the Sissenwine-Shepherd method using the Beverton-Holt stock recruitment parameters and SSB per recruit results generated by the SARC 41 ASAP model results. $\mathrm{B}_{\text {MSY }}$ was calculated using mean weights at age and is therefore comparable to mean biomass in year $t$. The 2010 estimate of mean total biomass is $140,297 \mathrm{mt}( \pm 1 \mathrm{std}$. dev. of $6,671 \mathrm{mt})$, which is slightly below $\mathrm{B}_{\text {MSY }}$ but well above $1 / 2 \mathrm{~B}_{\text {MSY }}$ of $73,526 \mathrm{mt}$. The 2010 estimate of fishing mortality ( 0.14 ) remains below $\mathrm{F}_{\text {MSY }}$. An alternative approach to estimating $\mathrm{B}_{\text {MSY }}$ is calculation of an equilibrium bluefish biomass when fished at $\mathrm{F}_{\text {MSY }}$, using a long term projection. This biomass, determined from a 50 year projection with re-sampling of

1982-2010 recruitment estimates, equaled 105,699 mt (Table 13). The comparable 2010 biomass estimate $(140,297 \mathrm{mt})$ is 1.33 times greater than this alternative $\mathrm{B}_{\mathrm{MSY}}$.

## Model Uncertainty

Model uncertainty can be characterized using the MCMC simulations to produce a distribution of possible outcomes given the model input parameters. However, these results do not capture the uncertainty from variations in the model input parameters. Forward projecting catch at age models are extremely flexible in applying weighting factors to emphasize either catch data or survey data. To illustrate the impact of changes to these weightings, as well as other factors, an ASAP model was run with changes to the effective sample size and changes to index lambdas and CVs to force the model to fit closer to the annual indices (Table 14). The resulting fishing mortality in 2010 was 0.19 with an SSB estimate of $94,362 \mathrm{mt}$, outside the $80 \%$ confidence interval associated with the MCMC simulation for the base model.

## Conclusion

The conclusion of the updated assessment is that the Atlantic coast bluefish stock continues above $\mathrm{B}_{\text {MSY }}$ while remaining below $\mathrm{F}_{\text {MSY }}$ and is not considered overfished or experiencing overfishing. The estimates of the model show little variation or significant retrospective patterns. The lack of variation is due in part to the fixed parameters for selectivity. Nevertheless, uncertainty remains in several aspects of the assessment input data. Age data continues to be limited to one age key from a limited set of samples. The assumption that this age information is applicable to all areas remains untested. Length samples from recreational discards are limited and contribute to the uncertainty as does the lack of commercial discard estimates. Changes in the NEFSC inshore survey series, from both vessel changes and sample area adjustments, significantly alter indices. Strata inshore of 15 fathoms are currently sampled as part of the NEMAP survey, but the time series is not yet adequate to provide a tuning index.

The highly migratory nature of bluefish populations and the recruitment dynamics of the species create a unique modeling situation. Migration creates seasonal fisheries with unique selectivity patterns resulting in a bimodal partial recruitment pattern. This
pattern has been identified in previous assessments as a source of uncertainty in the results and has been held constant in the model. The migratory pattern in bluefish also results in several recruitment events. A spring cohort, originating south of Cape Hatteras, NC during spring migrations, and a summer cohort originating in the offshore MidAtlantic Bight result in a bimodal age-0 size distribution. It has been hypothesized that the success of the spring cohort controls the abundance of adult bluefish. Future assessments should include any additional information that could index seasonal abundance of incoming recruitment.
